INDEX TO VOLUME II., 1923.

☞ *Readers in search of a given subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral, Heart and Cardiac, Liver and Hepatic, Child and Infant, Goitre and Thyroid, Diabetes, Glycosuria and Sugar, Eye, Ophthalmic, and Vision, Lunacy and Mental Disease, Arsenobenzol and Salvarsan, &c., &c. (Py Q) = Parliamentary Question. (R.) = Review. (L. A.) = Leading Article.*

A Concordance of page numbers and dates of Issue will be found at the end of the Index.

A

Abderhalden, Prof. Dr. E., Examination of Organs of Sense (R.), 1085 ; Biological Technique (R.), 1305
Abdomen, Acute, Early Diagnosis of (Mr. Z. Cope), 2nd ed., 1923 (R.), 520
Abdominal pain, chronic, in nervous women, 1347
Abdominal Surgery for Nurses (Mr. H. Burrows), 2nd ed., 1923 (R.), 1086
Aberdeen Medico-Chirurgical Society (see Med. Socs.)
Aberdeen University, pass-lists, 147, 312
Abortion, criminal, alarming increase in Austria, 1320
Abrahams, Dr. A., treatment of chronic colitis, 1411
Abscess, brain (Dr. G. Hadfield), 929 ; perinephric, 1140 ; liver, treatment by aspiration, 1324 ; (Dr. A. R. Neligan), 1398
Accidents du Travail (Léon Imbert and others), 2nd ed., 1923 (R.), 609
Acclimatisation, problems of (Dr. A. Balfour), 84, 243
Account-keeping, medical, simplified, 492
Acid-fastness, 78, 97
Acidosis and alkalosis in children, 360
Acromegalic stigmata, distribution of, 662
Acrostic, a double, 914
Actinomycosis, ætiology of (Mr. W. T. Warwick), 497 ; of head and neck, 1408
Acts, delay in publication of, 796
Adams, Dr. D., disseminated sclerosis, 1033
Adams, Dr. E. W., and Dr. H. N. Crossley, acute goitre in a children's home, 501
Advertisement, a criticised, 1118
Advertisements on medical certificates (Py Q), 310
Agar-agar, 1200
Agassiz, Dr. C. D. S., and Dr. S. R. Gloyne, tuberculosis in childhood, 25
Agate, Dr. H. St. A., pathological departments, 586
Age, A Green Old (Prof. A. Lacassaigne) (R.), 656
Air Force Medical Service (see Students' Guide), 422 ; the, nature and use of, 636
Albuminuria with unilateral œdema (Dr. J. W. Russell), 925 ; of pregnancy, 1008, 1057, 1110, 1133, 1210
Alcohol, Action of, in Man (Prof. E. H. Starling) (R.), 982, 1055
Alexandra Day at Brighton and Hove, 486
Alimentary secretion, mechanism of (L.A.), 288
Allbutt, Sir C., and Dr. P. C. Varrier-Jones, village settlements for the consumptive, 912
Allbutt, Sir C., integration of medicine, 977 ; opium in cardiac dyspnœa, 1422
Allott, Mr. E. N., lilliputian dosage, 631
Alpine therapeutics, post-grad. course on, 27
Alunozal, 1358
Ambulance, authority to engage, 89
American Posture League, 1003
Amœbiasis, pulmonary (Dr. P. Manson-Bahr), 599
Anæmia, secondary, in infancy (Dr. Helen M. M. Mackay), 165 ; pernicious (Py Q), 208 ; splenic, 290 ; sickle-cell, 1363
Anæsthesia, endotracheal insufflation, expiration in (Dr. I. W. Magill), 68 ; for children, 566 ; by the gas-oxygen-ethanesal and the gas-oxygen-chloroform-ethanesal combinations, 567 ; modern methods of, 1001 ; spinal, and its drawbacks (Dr. B. Desplas), 1233 ; (Prof. Dr. H. Finsterer) (R.), 1248 ; a surgeon's thoughts on, 1302
Anæsthesia, Practical Local (Dr. R. E. Farr) (R.), 889 ; Art of (Dr. P. J. Flagg), 3rd ed. (R.), 889
Anæsthetic, dental, for children, 141 ; from the surgeon's point of view, 301 ; sickness, treatment (Dr. J. Blomfield), 475 ; apparatus, improved, 938
Anæsthetics, acetylene and ethylene, 240
Anæsthetics, Handbook of (Dr. J. S. Ross), 2nd ed., 1923 (R.), 1248
Analytical Microscopy (Mr. T. E. Wallis) (R.), 20
Analytical Records (see Reports and Analytical Records)
Anatomy and Physiology, Text-book of (Dr. Elizabeth R. Bundy), 5th ed., 1923 (R.), 227 ; of the Human Form (Mr. U. W. A. Parkes) (R.), 937 ; Gray's, 22nd ed., 1923 (R.), 938
Anderson College of Medicine, opening address, 1001
Anderson, Dr. M. G., Obstetric Tables, 2nd ed., 1923 (R.), 937
Anderson, Mr. D., driving grip in golf, 154
Andrade, Prof. E. N. da C., Structure of Atom (R.), 1249
Andrews, Mr. J. A., modification of the Ringleb cystoscope, 1428
Aneurysm, arterio-venous, of neck (Mr. A. W. Mooro), 1186
Angina agranulocytolica, 1094
Angina pectoris, operations on cardiac nerves in (L.A.), 468 ; pectoris, prognosis in (Dr. J. Hay), 1119
Ankylostomiasis campaign in Madras, 1922, 475
Annual Charities Register and Digest, 1016
Anormale Kinder (Prof. L. Scholz), 3rd ed., 1922 (R.), 20
Ante-natal diagnosis (Dr. Frances M. Huxley), 321 ; care (Dr. R. A. Hendry), 548
Anthrax, origin and prevention of, 574
Antigen, defatted tubercle, 931, 955 ; pollen, prepared by Dreyer's method, 932
"Antimicrobum," Tomarkin's, 1310
Anwyl-Davies, Dr. T., and Dr. J. Mellanby, anticoagulating of arsenobenzols on blood, 555
Apex tracings, mechanical (Dr. A. Mougeot), 1182
Aphasia, dementia follows, 1254
Apnœa, inspiration, in a new-born infant (Dr. W. D. Kirkwood and Dr. B. Myers), 65
Apothecaries' Society of London, pass-lists, 43, 259, 487, 1012, 1279
Appendicitis, bilharzial, 28 ; caused by ascaris lumbricoïdes, 238
Appointments, weekly lists of, 49, 101, 152, 208, 263, 313, 368, 488, 538, 587, 633, 682, 815, 863, 910, 960, 1014, 1064, 1114, 1167, 1217, 1281, 1328, 1381, 1425
Approved societies and voluntary hospitals (Py Q), 100
Arey, Mr. L. B., twin tubal pregnancy, 27
Armstrong-Jones, Sir R., a correction, 1279
Army Medical Service (Py Q), 208 ; (see Students' Guide), 418
Aromatics and the Soul (Dr. D. McKenzie) (R.), 1086
Arsenical poisoning (work of Swedish Commission), 531
Arsenobenzols, anticoagulating action of on blood (Dr. T. Anwyl-Davies and Dr. J. Mellanby), 555
Arthritis, sulphur treatment, 80 ; chronic, treatment (Dr. W. H. Wynn), 617
Articulations, injuries and diseases of (Mr. A. G. T. Fisher), 541, 678
Ashby, Dr. H., after-results of abdominal tuberculosis in children, 362
Ashton, Mr. C. E., obituary, 1326
Ashworth, Prof. J. H., bearings of zoology on human welfare, 588
Aspiration, liver abscess treated by (Dr. A. R. Neligan), 1398
Association of Certificated Blind Masseurs, meeting, 60, 816
Asthma (Mr. F. Coke) (R.), 786
Asthma, treatment of (Dr. E. P. Poulton), 29 ; and protein idiosyncrasy and, 96 ; bronchial, due to mice, 131
Asylum superintendent's appointment (Py Q), 311
Atmospheric pollution, 577
Atom, new theory of (L. A.), 1041
Atomic Form (Mr. E. E. Price) (R.), 1086
Atomic physics, 616
Atoms (T. C. Wignall and G. D. Knox) (R.), 125 ; Studies of (Mr. B. Russell) (R.), 1249 ; Structure of (Prof. E. N. da C. Andrade) (R.), 1249
Avery, Dr. J. S., accidental vaccinia, 535
Augustus and Alice Waller Memorial, meeting, 1215

AUSTRALIA, CORRESPONDENCE FROM.—Government control of hospitals and charities ; Post-grad. teaching in Melbourne ; Hobart Hospital, Tasmania, 803—Insulin in Australia ; Australian Medical Congress, 804

Australia in the War of 1914–1918, Official History (Mr. H. S. Gullett and Mr. F. M. Cutlack) (R.), 835
Auto-pyo-therapy, 660
Ayurveda and Unani (L.A.), 659

B

Baby Week Conference, National, 33, 88
Bacillus coli infection, acute, of gastro-intestinal tract (Dr. R. C. Jewesbury and Prof. L. S. Dudgeon), 118, 874
Back, Mr. I., and Mr. L. Colledge, pharyngeal diverticulum, 1237
Bacteria digesting cellulose, 1198
Bacteriological Diagnosis (Von Dr. H. Schottmüller) (R.), 226 ; (Dr. L. Pincussen) (R.), 226

550572

Bacteriology, Practical (Surg.-Gen. E. R. Stitt), 7th ed., 1923 (R.), 607 ; Practical, for Chemical Students (Prof. D. Ellis) (R.), 607
Bailey, Dr. C. H., and Dr. E. A. Bullard, bilharzial appendicitis, 28
Baitsell, Dr. G. A., Evolution of Man (R.), 170
Balfour, Dr. A., problems of acclimatisation, 84, 243 ; Wellcome Bureau of Scientific Research, a correction, 631 ; director of the new School of Hygiene, 992
Balkan remedies for disease, 816
Bamford, Mr. D. St. J., private wards in London hospitals, 1058
Bankart, Mr. A. S. B., treatment of flat-foot, 799
Barker, Dr. L. F., Clinical Diagnosis of Internal Diseases (R.), 71
Barlow, Sir T., the late Mr. H. D. Farnell, 858
Barnes, Dr. H. A., Tonsils, Faucial, Lingual and Pharyngeal (R.), 567
Barnes, Eleanor C. (Lady Yarrow), Alfred Yarrow, his Life and Work (R.), 22
Barykin, Prof. W., and Dr. N. Kritsch, infecting agent of exanthematic typhus, 78
Bashford, Dr. E. F., obituary, 536
Beaton, causation of mental disorder, 121
Beattie, Prof. J. M., action of particles of slate on toxins, 668
Beatty, Dr. J., psoriasis, 1139
Beatty, Dr. W., death of, 1106
Béchamp or Pasteur ? (E. D. Hume) (R.), 1084
Beck, Dr. J. C., Applied Pathology in Diseases of Nose, Throat, and Ear (R.), 1356
Bedside table, invalid's, 286
Bee honey, New Zealand imperial, 1036
Bee-sting on the uvula, 864
Beers, Mr. C. W., A Mind that Found Itself (R.), 1084
Beit Memorial Fellowship, 131
Belfast Royal Victoria Hospital, retirement of Prof. T. Sinclair, 99
Bell, Prof. B., use of lead in treatment of malignant disease, 1425
Bennett, Dr. R. A., Hodgkin's Disease (R.), 610
Beri-beri in Madras Presidency, 35
Berkeley, Mr. C., use and abuse of forceps, 560
Berkeley-Hill, Maj. O., Ranchi European Medical Hospital, India, 122

BERLIN, CORRESPONDENCE FROM.—Title of " specialist " ; Meeting of Socialist doctors, 138—Control of new drugs ; Conditions in the Rhenish spas, 139—Prophylaxis of measles, 476—Medical men and the Profiteering Act ; Threatened strike of club doctors ; Combating the red ant ; Insurance against hospital expenses ; Quality of milk in Berlin, 477—Supply of medical books ; Model Rontgen institute ; 478—Care of war victims ; Accidents due to drunkenness ; Height and weight in children ; Treatment of tuberculosis, 622—Case of pneumo-peritoneum ; Regulation of medical fees ; First-aid huts in Berlin, 803—Changes in the Workmen's Insurance Act ; Letters patent for Dr. Friedmann ; Help to the Ruhr children, 1319—Venereal clinics, 1320

Bernhard-Smith, Mr. A., Poisonous Plants of all Countries, 2nd ed., 1923 (R.), 609
Bertrand, Dr. E. N. da C., Structure of the Atom (R.), 1249
Bertwistle, Dr. A. P., the silhouette radiogram, 783
Bethlem Royal Hospital, course of lectures, 1380
Bezançon, F., and S. I. de Jong, Maladies de l'appareil respiratoire (R.), 1034
Bianchi, Prof. L., on old age, 343
Biggs, Mr. H., death of, 91
Bigland, Dr. A. D., pellagra in British islands, 1295
Bilharziasis in Dongola Province of Sudan, 942 ; of ureter (Aly Bey Ibrahim), 1184 ; prevention of, 1372
Biliary system, secondary operations upon (Sir B. Moynihan), 4
Bing, Dr. R., Kompendium der topischen Gehirn- und Rücken - marksdiagnostik (R.), 281
Biochemistry and medicine (L.A.), 791 ; (Dr. C. Oppenheimer), 2nd ed., 1923 (R.), 1194
Biological Technique (Prof. E. Abderhalden) (R.), 1305
Biomathematics (Dr. W. M. Feldman) (R.), 463
Birmo, Swiss natural bitter water, 570
Birth control information (Py Q), 261 ; control and Ministry of Health, 1428
Birth injuries, intracranial, 1292
Births, illegitimate (Py Q), 101
Births, marriages, and deaths, weekly lists of, 49, 102, 152, 208, 263, 314, 368, 438, 489, 538, 588, 634, 682, 815, 863, 911, 960, 1015, 1064, 1115, 1168, 1217, 1281, 1328, 1381, 1425
Bismuthyl, bi-quinyl, and injectable urenile, 1358
" Black Jack " signature books, 1150
Blackham, Col. R. J., cows' milk in infant feeding, 361 ; correction, 859
Blacklock, Dr. B., ætiology of kala-azar and tropical sore, 273
Blackwater fever, ætiology of, 1362
Bladder, diverticulum of (L.A.), 467, 935 ; " idiopathic," hypertrophy of, 1191
Blair, Dr. Mary A., prophylactic treatment of puerperal sepsis, 95
Blake, Mr. F., case of exomphalos, 976
Blepharitis and styes (Dr. R. A. Greeves), 997
Blind, home care of, 92 ; welfare of, 660
Bliss, Dr. O., chronic tonsillitis and puerperal sepsis, 1363
Blomfield, Dr. J., anæsthetic sickness, 474
Blood and Blood Diseases (Von Dr. Med. O. Naegeli) (R.), 520 ; Sugar in Man, Investigations on (Dr. K. M. Hansen) (R.), 980 ; Grouping (Prof. L. Lattes) (R.), 1142 ; Pressure, High (Dr. J. F. H. Dally) (R.), 1250
Blood-fat and blood-sugar, inter-relationship of (Dr. T. H. Oliver and Dr. A. Haworth), 114 ; sugar, effect of bacterial extracts on, 370 ; donors, 585 ; pressure in new-born, 614 ; pressure, high (Dr. E. M. Brockbank), 880, 883 ; pressure in scarlet fever, 941
Bloxam, Mr. A. G., and Dr. S. J. Lewis, Bloxam's Chemistry, Inorganic and Organic, 11th ed., 1923 (R.), 1086
Board of Control, annual report, 662 ; for Scotland, report, 942
Boas, Dr. E. P., cardio-vascular complications of kyphoscoliosis, 471
Body, the wisdom of (Prof. E. H. Starling), 865
Boenheim, Dr. F., thymus extract as a therapeutic agent, 291
Boileau, Dr. Margaret, obituary, 679
Bonar, Dr. T. G. D., mastoid disease, 1079
Bone, carpal, semilunar, curious condition of, 943 ; marrow after splenectomy, 1254 ; necrosis after avulsion of scalp, 1310
Bones and Joints, Inflammation of (Dr. L. W. Ely) (R.), 334
Bonney, Mr. V., and Dr. H. M. McCrea, gynæcology and general medicine, 1025
Bose, Sir J. G., Life Movements in Plants (R.), 788 ; circulation and assimilation in plants, 1331
Bourne, Mr. A. W., acute salpingitis, 559
Bovinine, a raw food extract, 1144
Bowel, large, diseases of, 887
Bower, Prof. F. O., immobility of plant-body, 1220
Bowman, Dr. A. K., syphilis as a complication of tuberculosis, 1288
Box, Dr. C. R., London Fever Hospital, 1111
Boycott, Prof. A. E., action of alcohol on man, 1055
Boyle, Dr. H. E. G., anæsthesia by gas-oxygen-ethanesal and gas-oxygen-chloroform-ethanesal combinations, 567
Boyle, Mr. R., Ventilation of Public Buildings (R.), 282
B.P. codex, the new, 79
Bradbury, Dr. F. C. S., estimating urea in urine, 1246
Braeuning, Dr., is reinfection of tuberculosis from within or without ? 130
Branson, Dr. W. P. S., life assurance and syphilis, 472
Breast, Diseases of (Mr. W. H. Evans) (R.), 787
Breast, hypertrophy of (Mr. D. C. L. Fitzwilliams), 218 ; pump, hygienic, 636
Brighton and Sussex Med. Chir. Society (see Med. Socs.).
Brighton water-supply, 1215
Bristow, Mr. W. R., and Mr. C. M. Page, Fractures in General Practice (R.), 1355
British Association at Liverpool, 470 ; scientific exhibits, 616 ; atomic physics, 616 ; symbiosis in animals and plants, 668 ; diet and cancer, 668 ; action of particles of slate on toxins, 668 ; measurement of colour-blindness, 668 ; insulin and its value in medicine, 668 ; anthropology, 669
British Dental Association, annual meeting at Manchester, 294
British Jour. of Anæsthesia, 471
British Jour. of Experimental Biology, 615

BRITISH MEDICAL ASSOCIATION (Annual Meeting at Portsmouth).—(L.A.), 177—Public health policy, 185—Hospital policy, 188—Scientific work ; Medical Women's Federation ; Public health matters ; National Health Insurance, 189—Financial statement ; State recognition of opticians, 229—Notification of convictions to G.M.C., 230—Overseas branches ; non-panel practitioners ; notification of venereal disease, 231—Annual dinner, 232, 988
Section of Medicine.—Diabetes, 354—Heart disease in early life, 355—Chronic bronchitis, 357. *Surgery :* Obstruction of colon, 295—Operative treatment of malignant disease ; acute primary infections of hand, 298—Ventriculography, 300—Anæsthetics from the surgeon's point of view, 301. *Public Health :* Recent decrease in infant mortality, 302—Value of watercress ; sewer air, 303—Coal gas and ill-health, 304. *Laryngology and Otology :* Internal ear deafness, 358—Retrobulbar neuritis of nasal origin ; surgical treatment of nasal deformity ; spasm of larynx ; organotherapy in ear, nose, and throat work, 359. *Diseases of Children :* Acidosis and alkalosis, 360—Cow's milk in infant feeding ; summer diarrhœa, 361—After-results of abdominal tuberculosis, 362. *Neurology and Psychological Medicine :* Nervous child, 457—Sequelæ of encephalitis lethargica, 459—Prognosis of psychoses during adolescence, 461. *Tuberculosis :* Artificial light treatment, 511—Surgical treatment, 512—Social aspects, 513. *Ophthalmology :* Clinical significance of scotometry, 515—Ophthalmology and Navy, Army, and Air Force, 516. *Obstetrics and Gynæcology :* Acute salpingitis, 559—Use and abuse of forceps, 560. *Radiology and Electrology :* X ray examination of urinary tract, 562—Medical diathermy, 563. *Venereal Diseases :* Chronic gonorrhœal prostatitis and vesiculitis, 565. *Anæsthetics :* Anæsthesia for children, 566—Fatalities from anæsthetics ; anæsthesia by the gas-oxygen-ethanesal and the gas-oxygen-chloroform-ethanesal combinations, 567. *Exhibition :* Surgical instruments and appliances, 304—Drugs and pharmaceutical appliances, 305—Food preparations, 362 — Medicinal and mineral waters ; microscopes and scientific apparatus ; sundries ; medical agencies ; books and office accessories, 363

British surgeons in Denmark, 804
Broadhurst, Dr. J., How We Resist Disease (R.), 20
Brockbank, Dr. E. M., high blood pressure, 880, 883 ; Heart Disease, 5th ed., 1923 (R.), 982
Bronchitis, chronic, 357
Bronchomoniliasis (Dr. Th. Joekes and Dr. R. H. Simpson), 109
Brook Fever Hospital (Py Q), 149

THE CENTENARY OF THE LANCET

OCTOBER 5th, 1823—OCTOBER 5th, 1923.

THE FOUNDING OF THE LANCET.

THE first number of THE LANCET was issued on Oct. 5th, 1823, which was a Sunday, and the events of its first 20 years all centre round the actions of its founder. The founder of THE LANCET was Thomas Wakley, the youngest of the eight sons of a Devonshire farmer, and he was only 28 years of age when the first number of the journal appeared. The idea of producing a weekly paper was the outcome of a short but exciting personal experience as a practitioner and a chance acquaintance with William Cobbett. Cobbett was at that time making a series of political tours, traversing England on horseback, and publishing in his paper, the *Political Register*, his shrewd and eloquent criticisms of rural conditions. He had passed through an anxious and not wholly creditable period of his life, and he found himself winning a great position in letters by his championship of the cause of the weak generally, and by the frank advice which he was giving in his works of domestic and educational utility. To him Wakley confided his views upon the anxious position occupied by the rank and file of the medical profession at that date, and from him received the natural advice that he should get the arguments for reform in front of the reading public at the earliest opportunity.

MEDICAL TRAINING IN 1823.

Wakley's first-hand experience of the medical profession before he attempted to found a newspaper may be summed up as follows: He went to a London hospital and noted there conditions directly at variance with his ideas of justice. He found that, although the student might play his part in the educational scheme laid down by hospital authorities—namely, to pay fees and attend classes—the authorities at the hospitals were not prepared to play their part. The schools were insufficient in number, compelling the student to attend overcrowded private classes. The lectures at the regular schools were not delivered by the eminent people who received the fees, but by their demonstrators; the one great practical help to the acquisition of a sound knowledge of pathology, namely, presence at post-mortem examinations, was only secured by the clandestine feeing of porters in post-mortem rooms; the honorary staff, from whose lips the student was supposed to learn the science of healing, were capricious in their visits and were generally dumb upon the occasions when they appeared; the lists of operations were not published to the students at large, but only communicated to the favoured pupils of the staff, who knew what was going to be done by the great men and at what time. And how was the class of favoured pupils selected? Wakley found that the student could be relegated to a position in his profession, which was marked out from the beginning to be and to remain inferior, not in the least through want of personal merit, but entirely because he had not paid a fee to apprentice himself to a great man. Seeing that a popular operator, lecturer, teacher, or consultant adviser could ask and obtain high fees from his pupils, it followed that command of money at the beginning of a student's career might ensure success, while lack of money was condemnation to an inferior position. Wakley had no objection to being a general practitioner; on the contrary, he desired to be one. But having lived as a student for three years in the house of two hard-worked members of this class, sharing their labours and knowing their trials, and estimating the amount of good that they did and the amount of influence for good that they were able to exercise over the community, he recognised that these men were set on one side and looked down upon by their privileged brethren, who had themselves obtained their places in the medical hierarchy by purchase and not by merit. Wakley saw also that these fortunate ones, being in posts of office, took the emoluments and omitted to do the work. His sense of fairness revolted at these things, and none the less because he personally suffered from the abuses. The attitude towards hospital officials that he was soon to reveal, his readiness to find those superior beings wanting in skill, and his pertinacity in convicting them of unfairness and nepotism, were thus accounted for. As medical student, and as apprentice, Wakley had imbibed the belief that the doctor in general practice, like the student without financial backing, did not get justice, and that those who were wronging them were their leaders, who ought to have protected them.

A MYSTERIOUS OUTRAGE.

Immediately upon qualification as a Member of the Royal College of Surgeons of England, Wakley married and brought his wife to No. 5, Argyll-street, Regent-street, London, where, with his father-in-law's aid, he had acquired a practice; and it is interesting to know that the goodwill of the practice, situated in what was in 1820 a solid residential district, cost £400. Life was now running for him on an even keel. He had always the reforming spirit, but it seems quite likely that if this fortunate start had been smoothly continued his sense of grievance at the abuses in medical organisation would have abated and the regeneration of the medical practitioner would have awaited some other inspirer. But almost at once catastrophe fell upon him. In August of the same year in which he married a violent assault was made upon him by unknown ruffians, his house was gutted, and what property there was in it was destroyed or stolen.

The cause of the outrage was never exactly discovered, but a theory that the actions were due to revenge on the part of the followers of Thistlewood, a political desperado who had been executed recently, has considerable probability. It seems to have been widely rumoured that the masked man, stated to be a doctor, who beheaded Thistlewood, was Wakley. The Sheriff of London publicly contradicted the story, but the fact that such a contradiction was called for shows how substantial the rumour became. Wakley had to bring into court his claim against the company with which his goods were insured. This claim was settled, but not without considerable reluctance on the part of the company, who in the end paid the full amount under the terms of the policy and Wakley's costs, while the further expenses were defrayed by public subscription, the evidence having shown on which side right lay.

But though in this way Wakley's pecuniary loss was reduced to a small sum and his good repute before men was restored to him, the effects of the experience abided. He was paid in full, his name was cleared of the aspersions that had been showered upon it, while the public subscriptions to meet such of his costs as would otherwise have fallen upon himself constituted a public apology for the wrong that had been done him. But if his pecuniary loss was negligible and his character re-established, the effects of the circumstances of the past ten months remained and haunted him. They changed the tenour of his ways, forming the sharp stimulus that pricked him from the regular routine of the life of a general practitioner into a course of more free and individual assertion. He had been personally attacked, he had won, and a spirit of combat had been roused. During his time of trial he had found certain of his friends staunch and some of his immediate professional colleagues ready to repudiate for him the hard and evil things that were said of him; but the professional leaders, his teachers, and the College of which he was a Member did nothing. When, therefore, the strife of battle was over he was left an angry and unsettled man. There was not any shiftlessness in his hesitation to embark again in private practice; his reluctance was due to the feeling that he intended not again to be placed in so defenceless a position. He had prepared all things to live the life of a general practitioner of medicine. He had chosen his locality, and furnished his house to that end. Through no fault of his own the house had been destroyed, while enforced neglect of his practice had severed his connexion with his patients. It was necessary for him to start entirely afresh, and the ardent solicitude of a young husband was now replaced by the soreness of a disappointed man, who, though successful in obtaining his rights in a law court, had none the less been subjected to physical and moral savagery, and had lain under undeserved stigma at the moment when he was most in need of sympathy.

THE FIRST MEDICAL WEEKLY.

Wakley was a well-educated man as times went, and he wrote sound, forcible, and grammatical English with a facility and clearness which have been known to escape the highly cultured in our own day. His individual disappointments had turned a vigorous mind towards the reform of the abuses with which he connected the precarious position in which he found himself at the age of 28, and exactly at this juncture he met William Cobbett (Fig. 1), the link that bound them appearing to be that Cobbett, who was editor of the *Political Register* and the *Evening Post*, and the accepted Parliamentary candidate for Coventry, firmly believed that he at one time had also been destined to be a victim of the brutality of Thistlewood's maddened followers. He was 30 years Wakley's senior, was an eloquent propagandist and a brilliant journalist, and he inspired Wakley with the view that reform of the medical profession, which had become Wakley's *idée fixe*, could only be undertaken by the founding of a journal. Abuses similar to those which Cobbett and his school spied out in the body-politic were in the case of the medical profession clear; no one could deny that nepotism was rampant, that pecuniary traffic determined success, and that the educational curriculum was faulty. But the conditions were too special to lend themselves to general public treatment; no wide audience in a lay newspaper would have understood the hardships complained of without a tedious amount of preliminary explanation, whereas medical men, who had undergone the queer curriculum and were living by the exercise of a disorganised calling, would have no difficulty in appreciating the need for root and branch reforms. To deal with the situation THE LANCET was issued on Sunday, Oct. 5th, 1823, from the anonymous editor's dining-room in Norfolk-street, Strand, where Wakley had now established himself in a modest general practice; and while the contents were nominally addressed to public as well as medical readers, familiarity with professional situations was assumed.

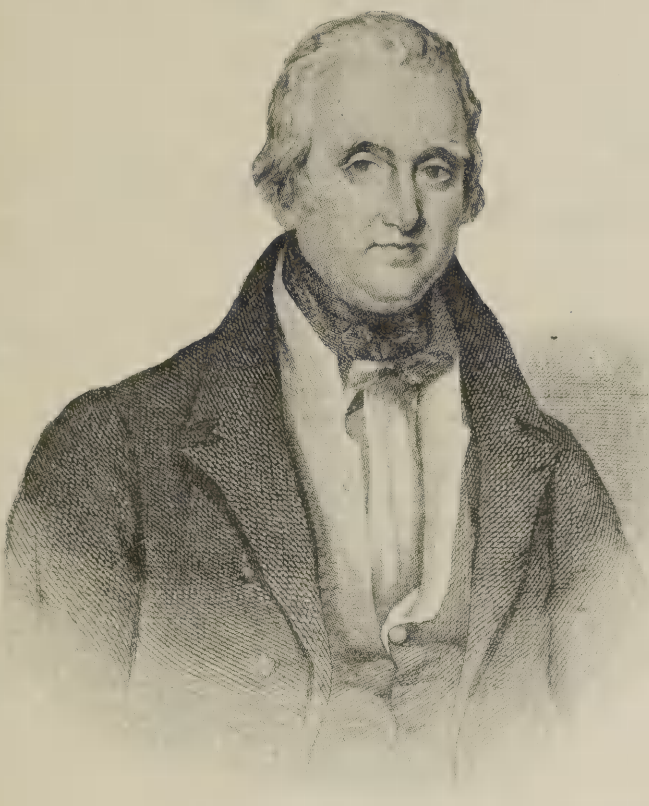

FIG. 1.—WILLIAM COBBETT.

The first number contained a prefatory statement to the effect that the objects of the new journal, which though inspired by London experience were not to be thus confined, would be :—

> "To produce a work that would convey to the public and to distant practitioners, as well as to students in medicine and surgery, reports of the metropolitan hospital lectures."

And, secondly :

> "To give a correct description of all the important cases that may occur, whether in England or on any part of the civilised continent."

And, as though this programme was not sufficiently inclusive, Wakley added to his promises the following :—

> "Our columns will not be restricted to medical intelligence, but, on the contrary, we shall be indefatigable in our exertions to render THE LANCET a complete chronicle of current literature."

We may note how far in the space of 36 small octavo pages it was attempted to keep the promises made. The metropolitan hospital lecture selected for report was one delivered on Oct. 1st, 1823, by Sir Astley Cooper, and it is a good example of chatty exhortation to a medical school, the students present being described by the Editor—it may be feared with an eye on possible subscribers—in these words :—

> "We never before witnessed so genteel a surgical class; the sight was most pleasing, for they all appeared gentlemen of cultured manners and good education."

A leading article succeeded entitled "Politics," which showed that it was the editorial intention to rely upon the Radicalism of Cobbett's school for general social views. Some notes on the drama were followed by three carefully written clinical cases from Newcastle-on-Tyne, from Lynn in Norfolk, and from Bedford, indicating the design to excite the interest of widely separated centres. Then came a long quotation, under the heading Medical and Surgical Intelligence, from the columns of a monthly medical journal, the *London Medical Repository.* In this excerpt Mr. Henry Earle, assistant surgeon to St. Bartholomew's Hospital, carries on a controversy with Sir Astley Cooper as to whether fracture of the neck of the thigh-bone ever unites, and also as to whether Cooper had said that Earle was maintaining the contrary view in order to depreciate Guy's Hospital and its teaching—for Cooper, while lecturer at St. Thomas's Hospital, was surgeon to Guy's Hospital. From the journalistic point of view there was considerable sagacity in publishing in the first number of the new medical paper, and in the front pages, an address by the acknowledged leader of surgery, while reprinting, as a quotation, a very civil but candid reflection upon his judgment. This article struck that note of criticism without fear of persons which Wakley intended should be characteristic of his venture, and which, as we shall see, involved him in a group of actions for some ten years. The offer to supply a "complete chronicle of current literature" was met by quoting from the *London Magazine* a letter by "Elia" to Robert Southey, whom the Editor of THE LANCET described as a "sack-hunting hypocritical rhymer," thus expressing the opinion of the Radical party upon the Poet Laureate. A short paragraph, which promised mysterious revelations concerning a clergyman, led to the editorial request for certain information concerning that person, with which the number closes. Having regard to the direction which those revelations afterwards took, we cannot be surprised that in the second number the Editor of THE LANCET has changed his printer.

The following is the first title-page in facsimile (Fig. 2).

THE FIRST TEN YEARS.

A FIERCE STRUGGLE.

FOR the first ten years of its existence THE LANCET was a duelling ground for a series of fierce encounters between the Editor and the members of the privileged classes in medicine. The lectures of certain of the great hospital surgeons and physicians were reported in its pages to the exasperation of the lecturers, and the delight of the profession at large and the students. The great men feared that their fees as teachers in the metropolitan schools would diminish if the cream of their teaching could be bought for sixpence a week instead of £5 a session; while every medical man or student, unable by circumstances to attend the classes of his leaders, rejoiced in the chance offered to him of acquiring familiarity with their methods and theories through the medium of print. The meetings of the medical societies, again, were reported at such length as their importance appeared to warrant—a proceeding which the officials of the societies objected to as an infringement of copyright. They considered that the editor of the Transactions of the Society, a person appointed by themselves, enjoyed the copyright as a matter of common sense as well as common law. These officials belonged, as it was quite right that they should, to the class from which the honorary staffs of the hospitals were selected, and they thus felt doubly outraged. Briefly, from the beginning the hospital surgeons and physicians were ranged in unbroken phalanx in opposition to the new and, as they considered it, mischievous print. The officials of the medical societies followed suit; and the office-bearers of the medical corporations, the practices of which were scathingly reviewed in early issues of THE LANCET, were not slow to scent their foe. Everyone who had anything to gain by the peaceful reign of existing methods in school, hospital, or corporation—a definition which included most of the influential members of the profession—looked with uneasiness at the growing power and popularity of the new journal. Especially were they frightened at the new idea that medical affairs could be treated as an ordinary, though elevated and important, section of human activity, and they were positively shocked to see the common rules of justice and the prevalent methods of business quoted publicly in connexion with these affairs, which they had been bred to consider sacrosanct.

Wakley for his part was quick to discover his enemies, and their tactics dictated his. For the first few weeks THE LANCET attracted no particular attention, and such notice as it received was complimentary. Then a few of the privileged classes became frightened, and in return sought to frighten Wakley. They denounced him as a literary pirate and a disseminator of moral garbage. His replies were chiefly in the nature of reflection on the complete and fretful ineptitude of his denunciators. He pointed to his growing circulation, scattered, with doubtful taste but cruel point, a few nicknames, and hinted at astonishing revelations of abuses arising out of the fact that publicity had hitherto been avoided by hospital officials. As a natural pendant to his assertion that the elections of the staffs of the various metropolitan hospitals were made at the instigation of pure nepotism, accounts were given of maladministration in the schools and malpraxis in the wards. And upon these came action and cross action. Certain of the criticised were compelled to proceed legally against their critic, while their defence outside the law courts, too keenly and bitterly undertaken by friends or rival journals, on more than one occasion laid the defenders open to counter charges of misrepresentation. In the first ten years of the existence of THE LANCET the paper was engaged in no less than ten actions, its opponents being eight separate persons. The proceedings in these various actions constitute an interesting phase in the history of medical reform. Six were for libel, the aggregate sum of £8000 being claimed for damages; the aggregate sum of £155 0*s*. ¼*d*. was awarded, while the Editor's costs were largely defrayed by public subscription. The articles complained of may have been indecent journalism—thus those who suffered never wearied of saying; but they were certainly truthful in all the essentials. Reference in some detail will have to be made to certain of these cases, but it should be remembered that personal libel constituted only an episode in the design of the paper. That the Editor himself revelled in a row led to a disproportionate prominence being given to events which were the necessary accompaniment to a brave policy of reform. The two things which came almost at once to constitute the design of the paper were: (1) To supply medical information which was available at that time to but few people; and (2) to show that hospitals were not served, and that students were not trained, by persons selected for their merits. The libel actions arose out of the publication of supporting evidence, and ceased as reform followed.

COPYRIGHT IN LECTURES: THE ABERNETHY CASE.

The publication of Sir Astley Cooper's lectures in the place of honour in the new paper proved a fine venture. Their issue was unauthorised, but the view of Wakley and his supporters was that no permission was needed for the publication. The lectures attracted and held readers, and hardly less important from a business point of view was the prestige that their publication at once conferred upon THE LANCET. Sir Astley Cooper (Fig. 3) was at the highest point of his professional fame, his unrivalled reputation being enhanced by wealth, personal attractiveness, popularity, a recent baronetcy, and a high position in the social world. As long as Cooper himself did not resent publication of his lectures the frightened owners of vested interests were unable to cry down the paper as a gutter production. As a matter of fact, Cooper went further, probably being soundly advised that his rights in the matter would be difficult of definition. He said that the publicity which was being afforded to him by the publication of his lectures with his name attached, excerpts from which were appearing in the daily papers, exposed him to the critical gaze of professional brethren; but he added: "I care not who may be acquainted with the doctrines I advance, the instructions I give, or the principles I inculcate whilst in this theatre; therefore I am perfectly indifferent as to who publishes them and equally indifferent as to who may be made acquainted with them." Later, however, he made a modification of this view. On learning that THE LANCET, the secret of whose editorship was at first complete, was produced by an old pupil at the United Hospitals of Guy's and St. Thomas's, Cooper called on Wakley in the character of a patient, and caught him in the act of correcting a proof of one of the lectures. He there and then entered into a compromise under which no objection would be raised to the publication of the lectures if the name of the author was suppressed. The young Editor, having reaped the advantage accruing from a known association with the great Sir Astley, agreed that it was not the name but the teaching that mattered, and accordingly, after the fifteenth lecture had been published, the communications became anonymous.

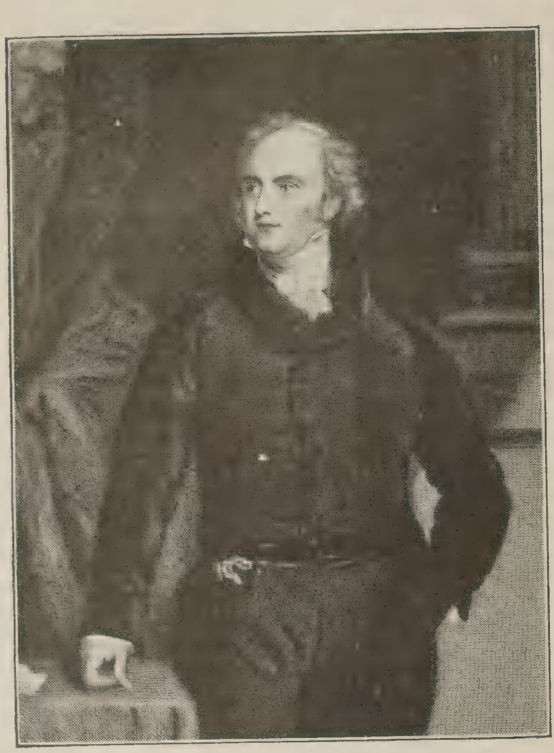

FIG. 3.—SIR ASTLEY COOPER.

But the famous Abernethy (Fig. 4) in the following year took a different line, and on the appearance of his clinical lectures in THE LANCET instituted proceedings which have had considerable influence on the law of copyright. Abernethy was backed by many of his colleagues, who said that the whole thing savoured of advertisement, and who may have felt that the revelation of their educational methods would not always redound to their credit. Abernethy objected to transcripts of his lectures, and was ill-advised enough to say, further, that the reports were inaccurate. THE LANCET accordingly reported one of Abernethy's lectures exactly as he delivered it. Abernethy's bluntness and colloquial conversation were notorious, and this is the sort of thing which was published:—

> "If I am wrong I shall be very happy to have my errors pointed out and corrected. I'll be hanged if erysipelas is not always a result of a disordered state of the digestive organs. . . . Egad, it is a travelling disease, and, as I say, the parts are disposed to swell. . . . If it be seated in an unimportant part, in the name of G— let it go there. . . . O, said the dresser, it is a case of erysipelas, and he only came in last week. Good G— said I, is it possible?"

Abernethy found it embarrassing to read his expletives in cold print. He was second only to Astley Cooper in the surgical hierarchy of London, he was regarded with peculiar reverence as the exponent of John Hunter's teaching, and he brought an action for an injunction against Wakley, the printers, and the publishers. In the first stage of the case before Lord Eldon, Wakley successfully resisted an attempt to obtain the injunction, when the *London Medical Repository*, politely referred to by Wakley ever afterwards as the "Mausoleum," expressed the view, in the picturesque language of the time, that the action of THE LANCET was no better than thieving. There immediately appeared in THE LANCET an article daring Abernethy to attempt to interfere again with the publication of his lectures. It was pointed out that it was of public importance that these lectures should be good, inasmuch as, by a by-law of the Royal College of Surgeons of England, recently framed by the Court of Examiners, of

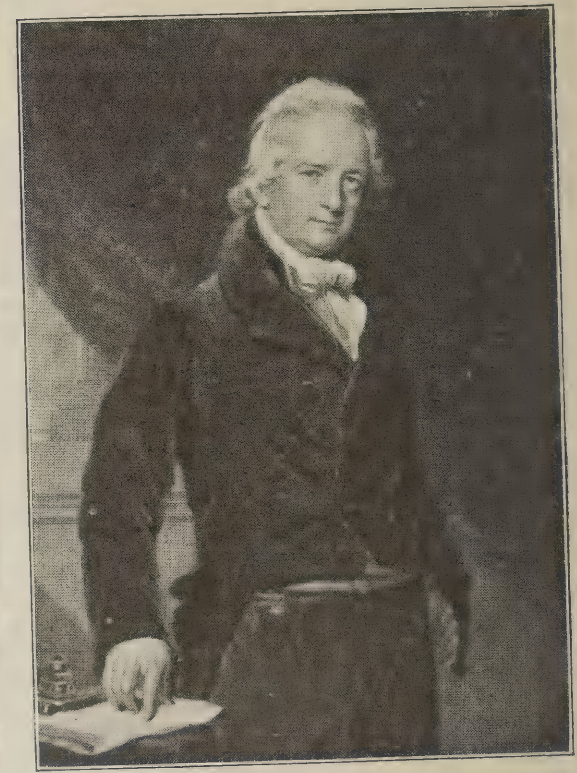

FIG. 4.—JOHN ABERNETHY.

which Abernethy himself was at the time a member, the London students could not abstain from attending Abernethy's lectures if they wished. This by-law compelled all the medical students in London to attend lectures by some five persons, of whom Abernethy was one, and the wrong that could be done under the exercise of such authority seems to have been the first thing to direct the attention of THE LANCET to abuses within the College. But from this moment the policy and procedure of the College were always submitted to close scrutiny.

At this time only six London hospitals possessed medical schools—namely, St. Bartholomew's, St. George's, the London, Middlesex, and the United Hospitals of St. Thomas's and Guy's; Westminster Hospital was at the time a dispensary, Charing Cross Hospital can be best described as a large ambulance station, University College and King's College respectively came into existence in 1833 and 1839, and St. Mary's Hospital dates as a separate entity from 1845. So when it was pleaded for Abernethy that the publication of his lectures was likely to lead to the diminution of his surgical classes, and therefore to abatement in his fees, Wakley, who knew that this could not happen, wound up a leading article by saying, "In the name of God don't let us hear any more of such loathsome trash."

Abernethy immediately made a second application for an injunction and thereon occurred a stalemate. The Lord Chancellor went back on himself, and Abernethy now secured the judgment, but shortly afterwards the injunction was dissolved upon a motion from Wakley's side, Wakley in the meantime having published addresses by Abernethy precisely as if no injunction existed, on the grounds that the lectures were delivered in a public capacity. The new argument placed in Wakley's hands was supplied by Abernethy himself, who tendered his resignation as a surgeon to St. Bartholomew's while desiring to remain a lecturer. The governors refused to accept his resignation as a surgeon unless he gave up his lectureship. That proved, said Wakley, that the lectures were delivered in a public capacity as surgeon to a public charity, while a certain section of the students of the metropolis must attend them whether they liked or no. The argument was uncontroverted and Lord Eldon removed the restriction.

And now legal action followed indirectly upon the publication of Sir Astley Cooper's lectures. For these appeared in book form, edited by Frederick Tyrrell, a colleague, when Wakley, smarting under a good many accusations of having stolen Astley Cooper's work, asserted that the text of the lectures, as now published, had been bodily stolen from THE LANCET, a few illustrative, and mostly unimportant, cases having been tacked on. The plagiarism could not be denied, nor could the fact that the clinical notes added were seriously inaccurate, but such was the venom of Wakley's remarks on the subject, so thoroughly did he hold up the unfortunate Tyrrell to contempt, that he can hardly have been surprised when Lord Chief Justice Best fined him £50 after an action for libel. Lord Chief Justice Best thought that the author had been libelled not so much by the things said as the way in which they were said. The fine and costs were immediately paid by public subscription.

The law of copyright in lectures under the old Act was not very clear or definite, but the Act 5 & 6 Will. IV., c. 65, has been repealed, and lectures, as well as all other copyright property, are now governed by the Act of 1911, which came into operation July 1st, 1912. Common Law right in the matter of copyright property has been done away with, and everything depends on statute in the case of an unpublished work "at the date of making the work, if the author is a British subject or resident within His Majesty's Dominions." Copyright under the statute means "the sole right to produce or reproduce the work or any substantial part thereof in any material form whatsoever, to perform or in the case of a lecture to deliver the work, or any substantial part thereof in public." Under section 35 "lecture" is defined to include "address, speech, and sermon." Under section 1, subsection 3, of the Act, "publication" does not include the "delivery in public of a lecture," and under section 2, subsection 1, par. v., the following act shall not constitute an infringement:—

> "(v.) The publication in a newspaper of a report of a lecture delivered in public, unless the report is prohibited by conspicuous written or printed notice affixed before and maintained during the lecture at or about the main entrance of the building in which the lecture is given, and, except whilst the building is being used for public worship, in a position near the lecturer; but nothing in this paragraph shall affect the provisions in paragraph (i.) as to newspaper summaries."

And paragraph (i.), as to newspaper summaries, runs as follows:—

> "(i.) Any fair dealing with any work for the purposes of private study, research, criticism, review, or newspaper summary."

From this statement it is clear that an elaborate reproduction of a lecture is forbidden when the requisite notice is affixed, but, notice or no notice, a reasonable newspaper summary is not an infringement. These restrictions only refer to the delivery of a lecture in public. When a lecture is delivered privately—there have been various legal decisions on the point—then any public report is an infringement of copyright. The present position has been reached largely through the original action of THE LANCET in publishing Sir Astley Cooper's lectures.

MALPRAXIS IN HOSPITALS: THE BRANSBY COOPER CASE.

Of the innumerable small quarrels that arose and were threshed out in its columns during this decade it will serve no purpose to speak. They would not be illustrative of anything in Wakley's character that is not sufficiently made clear already. They were but episodes in a contentious career, the border warfare incidental to Wakley's invasion of the privileges of the leaders of the profession. But his fight for the right to print the lectures of hospital surgeons and his determined attacks upon hospital practice, when wrongly carried on, must be looked upon as organised campaigns. These formed one-half of his policy of aggression as a reformer; the other half was formed by a crusade against the Royal College of Surgeons of England.

If the publication of their lectures aroused irritation and even apprehension, the suggestion to publish notes of the proceedings in the operation theatres aroused fury in the staffs of the hospitals. Wakley, however, announced his intention of reporting operative procedures for the instruction of the general medical constituency, and when he found that his reporters were to be excluded from the operating theatres he declared war, stating that he believed that it was in the interests of the public that such reports should be made, and that only those people who were afraid of publicity—persons whom he persistently called "hole-and-corner surgeons"—would have any legitimate objection. Accordingly reports were published from the various operating theatres, even when the walls were placarded with prohibitions. The exclusion of the supposed emissaries of THE LANCET did not stop notes of all proceedings regularly appearing in the paper, and the articles were for the most part so well and temperately done that the connivance of the staffs was perfectly certain. Everyone could see that Wakley was helped from the inside in his criticisms of hospital practice, as he was later in his denunciation of the Council of the Royal College of Surgeons of England. But all the hospital reports were not favourable to the operators, malpraxis being noted at St. Bartholomew's, Guy's, St. George's, and St. Thomas's, and severe comments were sometimes added. Thus the writer of a report of an operation for strangulated hernia at the Middlesex Hospital went so far as to say that, seeing the unfortunate patient's plight when the operation was conducted, he could only conclude that it was the practice at the Middlesex Hospital for the surgeons to wait before operating until all chance of recovery had gone; and he added that only one patient had recovered from an operation for strangulated hernia at that hospital in the course of two years.

Many members of the London hospital staffs were incensed at such criticisms of themselves and their class, but the report of a lithotomy operation at Guy's Hospital by Mr. Bransby Cooper (Fig. 5), a nephew of Sir Astley Cooper, brought matters to a head. It was written in so malignant a style that the terrible mischief, as well as the power, of sensational journalism was remarkably illustrated by it; it was at once the very best and the very worst that such a report could be. The story was cast in dramatic form. It was divided into Act I. and Act II., while the result of an examination of the body after the death of the patient was added as an epilogue. The first Act set out the preliminary steps of the operation, which took 20 minutes, and clearly insinuated that, the original incision having been wrongly made, the operator lost his proper appreciation of the anatomical geography of the region, and attempted violently to effect a passage with his forceps where no incision had cleared the way—that in his attempts to reach the bladder he made a false passage. The second Act, stated to have lasted half an hour, accused the operator of having hopelessly lost his head. It described him as calling for all forms of instruments, notably for one, the scoop, that must have been useless until the foreign body was actually located; as asking for the assistance of his colleagues, and even his dresser; as complaining in front of the patient, of course unnarcotised, of his utter inability to understand the cause of failure to extract the stone; and, finally, when at last the operation was over, of attempting to explain the difficulties to the appalled assembly of surgeons and students, while the conscious and dying patient still lay bound upon the operating table. No more terrible picture of incompetency, of want of skill, want of nerve, and want of heart could be imagined than the picture that was drawn, and the epilogue was in keeping. A brief description of the parts concerned in the operation was followed by the most unmistakable insinuation that the reason why Mr. Bransby Cooper had failed to extract the stone from the patient's bladder was because his forceps had not been in the bladder at all.

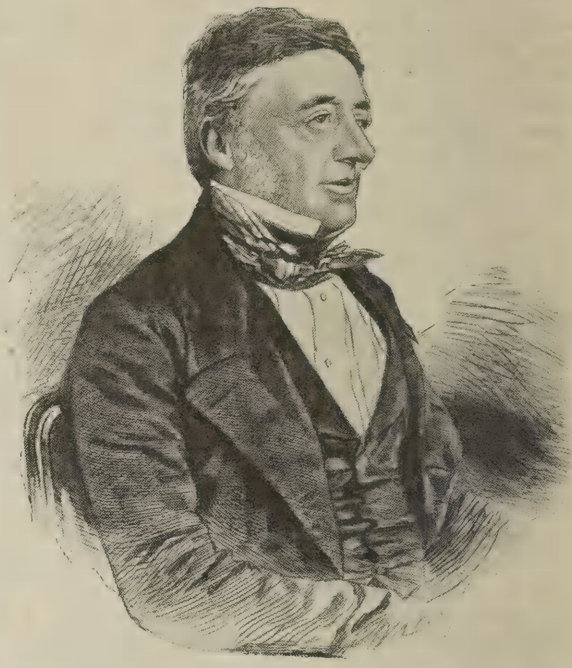

FIG. 5.—BRANSBY COOPER.

Stripped of all verbiage, the report meant that the authorities of Guy's Hospital had elected Mr. Bransby Cooper upon their staff because he was Sir Astley Cooper's nephew, that he had killed a patient by gross mistakes during an operation, and that he was so concerned at his exhibition of ignorance that he behaved with callousness to the sufferer. Nepotism on the part of the management and malpraxis on the part of the executive had been Wakley's accusations against the London hospitals, and now one set of circumstances appeared to him to prove that he was right in both directions. An action for libel immediately followed on the publication of the report, when Wakley was not entirely happy in his witnesses. It was fairly obvious that some of the information with which he had been supplied had been given in confidence, and that the informer could not be asked to vouch for it in a law court, and publicly. But, on the whole, the paper was able to maintain the accuracy of the article. A group of distinguished surgeons and pathologists spoke in behalf of Bransby Cooper: his excellent training, his creditable record, the difficulty of the operation, the possibility of anatomical abnormalities were all sworn to, and the jury, after an absence of two hours, delivered a verdict for the plaintiff of £100. It was clear that the jury believed the main statement that malpraxis had occurred, for on no other ground could they have let off THE LANCET so cheaply, having regard to the things printed. What had already happened in the Abernethy case happened in the Bransby Cooper case; the jury considered that THE LANCET had justified the main thesis, but ought to be fined for indecency of language. A public meeting was held on the following day, resolutions were passed that THE LANCET was conducted in the best interests of medical reform, and that a subscription should be opened to defray the expenses of the late action. Wakley asked for £408 7*s.* 9*d.*: £295 10*s.* Mr. Bransby Cooper's costs; £100 the plaintiff's damages; and £12 17*s.* 9*d.* otherwise made up. The sum was subscribed in the room, and certain subscriptions which reached the secretary later were given to the widow of Bransby Cooper's patient.

A FIGHT WITH AUTHORITY.

A FULL account of the constitution of the Royal College of Surgeons of England is outside the scope of this short contribution to medical history, but the headings of the story must be given to make the conduct of THE LANCET for a long period intelligible.

THE CONSTITUTION OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

By the Act of 1745 it was enacted that the Master of the Company which was the precursor of the College, and at least one of the governors, should be represented at every Court with one or two Assistants to constitute a quorum. It happened that in consequence of the death of one governor and the illness of another no legal Court was possible on certain occasions, when the Master and Assistants proceeded to business notwithstanding. Accordingly a Bill was brought before Parliament to legalise what had happened, and to reconstruct the Company as a College. A petition in opposition caught up this Bill when it had passed the Commons unnoticed and was in its final stage before the Lords. Lord Thurlow defended the privileges of the aggrieved Members of the corporation, who rightly considered that, if the maladministration were made legal, their privileges would disappear, whether the body were termed a Company or a College. The Bill was thrown out, but shortly afterwards a Royal Charter was obtained in an unexpected manner. For in the meantime the Company had accepted charge of Hunter's Museum, for which Parliament had voted large sums of money, and it became sound public policy to dignify its position. The new Charter sanctioned provisions which had been contained in the previous and rejected Bill, and when THE LANCET was founded this abuse was comparatively recent. It served as a weapon in Wakley's hands as soon as he became aware that the general designs for medical reform which he and a progressive staff of writers were advocating were finding in the College a powerful adversary. The chance of THE LANCET lay in a by-law passed by the College in 1824, making it compulsory for students to attend the lectures of certain hospital officials, the regulation to which reference has already been made. Certain of these lectures were being published in THE LANCET, and the contemporary medical press was excessively disturbed in its sense of what was right thereby, and freely called the editor a robber. But if the lectures were compulsory for the students before they could take their diplomas, the private character claimed for them by Abernethy and others was destroyed. A newspaper would have an undoubted right to report them, because it was to the public benefit to know whether instruction which the London medical man must receive was worth receiving. Lecturers chosen in this manner by the Council of the College were constituted public officials in their capacity as lecturers, and in addition to the importance and substantial fees thus ensured to them, could not claim all the privileges enjoyed by private individuals.

In another way THE LANCET was concerned in the working of this by-law. Some of the hospital surgeons appointed as the only persons whose lectures would be considered official by the Royal College of Surgeons of England charged their classes very large fees for attendance. Wakley had not been an affluent student, and had known many men poorer than himself, and he inveighed against the extraction of fees from their pockets for listening to lectures from persons whom he considered inferior surgeons.

The wording of the by-law was as follows :—

> That certificates of attendance at lectures on anatomy, physiology, the theory and practice of surgery, and of the performance of dissections be not received by the court except from the appointed professors of anatomy and surgery in the University of Dublin, Edinburgh, Glasgow, or Aberdeen, or from persons teaching in a school acknowledged by the medical establishment of one of the recognised hospitals, or from persons being physicians or surgeons to any of these hospitals.

It will be seen that this by-law conferred upon the surgeons and lecturers—they were the same persons—of the metropolitan hospitals authority and monopoly in the education of the London students at a time when Wakley was attempting to show that these persons were elected upon corrupt principles.

The story was well set out in a letter to THE LANCET written by the witty James Wardrop (Fig. 6), whose name may still be familiar from its occurrence in some text-books of surgery as the originator of the treatment of aneurysm by distal ligature. The letter purported to be addressed to the Court of Examiners of the College, but was really designed to catch the attention of the Members and to summarise their obvious grievances. It rallied the Court of Examiners on their senility, as proved by their recollection of remote events and ignorance of recent happenings, and recalled the fact that in 1797 an attempt had been made by the then Company, the Corporation of Surgeons, to be erected into a College under a Bill indemnifying the authorities of the Corporation and depriving the commonalty of their rights. According to Wardrop this Bill was rejected because the Corporation had received in fees and quarterages money which they had spent on themselves, and he said that Parliament had become aware of the fact. Two years later, as we have seen, the Corporation accepted the charge of Hunter's Museum, and obtained a Royal Charter for the purpose, which Charter sanctioned most of the provisions contained in the rejected Bill. Wardrop's point was that, while Parliament had refused to pass a Bill which excluded the commonalty from a share in the government, a Royal Charter had subsequently deprived them of legal rights to the franchise, this being also the contention of THE LANCET. But Wardrop added a description of the way in which the College at that time interpreted the charge of the Hunterian Museum:—

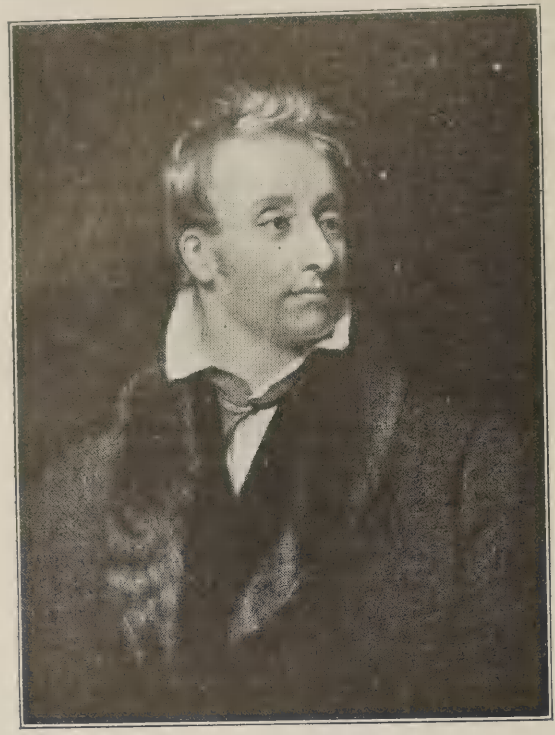

FIG. 6.—JAMES WARDROP.

> "I need hardly remind you, Sir," he wrote, "that the magnificent collection of John Hunter was purchased by Government, and that a loan of a large sum of money was supplied from the same source to erect a suitable building for its reception. Do you think the motive for such liberality was that 21 persons should have power to lock up the museum for eight months in the year? When their Bill was before the House of Lords it was said that they had a theatre without lecturers and a library without books. It is true that we have now some lectures on comparative anatomy and surgery; but the man best qualified to give the lectures on the former subject is doomed to fill the servile office of conservator of the museum. They have also books, and some years ago Sir William Blizard promised that the library should soon be opened. We are still outside the door, however, and a part of the bust of Sir William, like the molten calf of the Israelites, may go down our throats (by the adulteration of bread or the drinking of soda-water) before we shall see a book, especially the Hunterian MSS. The museum is opened twice a week during four months in the year; the hours of admittance are from 12 to 4 o'clock. This does not extend to the whole collection, for the gallery is only accessible from 12 to 2 o'clock. Should the extensive and varied information and indefatigable kindness of the conservator of the museum, Mr. Clift, tempt an unfortunate individual to remain a minute after the clock has struck the hour his crime is announced by the loud and angry sound of the beadle's bell. This noisy warning is very quickly repeated, and lest he should not understand it the beadle calls out in a most autocratic tone, 'This way, Sir.' The College Member descends the steps muttering perhaps, as I have done, 'Any way but this way, Sir.'" (Fig. 7.)

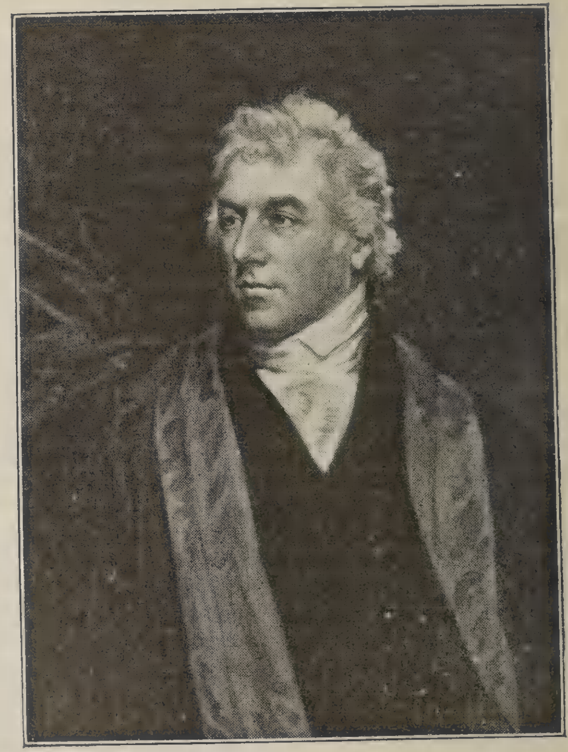

FIG. 7.—SIR WILLIAM BLIZARD.

The apparent purpose of the by-law, it must be admitted, was to aggrandise the hospital surgeon, at whose disposal it placed the lucrative post of lecturer, giving him a monopoly in the payment for and management of the medical education of the student.

AGITATION: CONSTITUTIONAL AND OTHERWISE.

The attitude of THE LANCET for several years became increasingly inimical to the Royal College of Surgeons of England, and not only because it was the offending by-law which led to the action with Abernethy, or because the expert witnesses for the plaintiff in the Bransby Cooper case were high officials in the College. The constitution of the College was an outrage to the radicalism which underlay the theories and practice of all the early staff of the paper. When Wakley maintained that the by-law making it compulsory for medical students to attend the lectures of certain hospital surgeons was a direct way of extracting from the pockets of students large fees for attendance upon the lectures of College officials, and when he associated the College with the nepotism which he was exposing at the hospitals, he was really shaping, almost unconsciously, for a great revision of medical education, and a standardisation of the professional calling. As this became clearer he obtained warm assistance from within the College, sometimes anonymously and sometimes openly, as in the cases of the famous Sir William Lawrence (Fig. 8) and Wardrop. To the credit of Tyrrell, who had been driven to law by Wakley's acrimony, he was also to be found among Wakley's open supporters. A meeting was now organised by THE LANCET, with Lawrence in the chair, of Members of the College, when a resolution was passed that a petition should be presented to the House of Commons for a new Charter. Abernethy rejoined with a circular putting out the views of the Council of the College, in a long explanation of the good work done by the examiners, and of the solicitude with which the Hunterian Museum was cared for. But owing to the general feeling with regard to the destruction of Hunter's manuscripts the last plea counted for nothing, and the movement went forward. The petition was presented, and on the motion of Henry Warburton (Sir Robert Peel, Home Secretary, having at the last moment refused support) the House acceded to the motion, and the College was bidden to render an account of its stewardship.

The prompt victory, however, proved an entirely barren one, for when the matter came to debate there was no one in the House sufficiently well-informed to meet the substantial opposition. Wakley's supporters did not, however, lose heart, and the altercation was carried into the very precincts of the College, and became a literal and physical battle. The occasion arose in a comical manner. Advantage was taken of an official mistake which excluded naval surgeons from the levées of the Sailor King. A party of reforming Members attended the delivery of a Hunterian lecture, and before the lecturer entered Wakley rose and delivered an oration of his own, which resulted in a resolution being passed calling on the Council to vindicate the rights and dignities of its Members in other ways as well as by insisting upon proper treatment of the surgeons of the navy. The resolutions were laid before the Council after the Hunterian lecture, when by a majority of 15 to 3 the Council found themselves unable to act upon them, though the three most important men on the Council—Sir Astley Cooper, Sir William Lawrence, and Sir Benjamin Brodie—formed the minority.

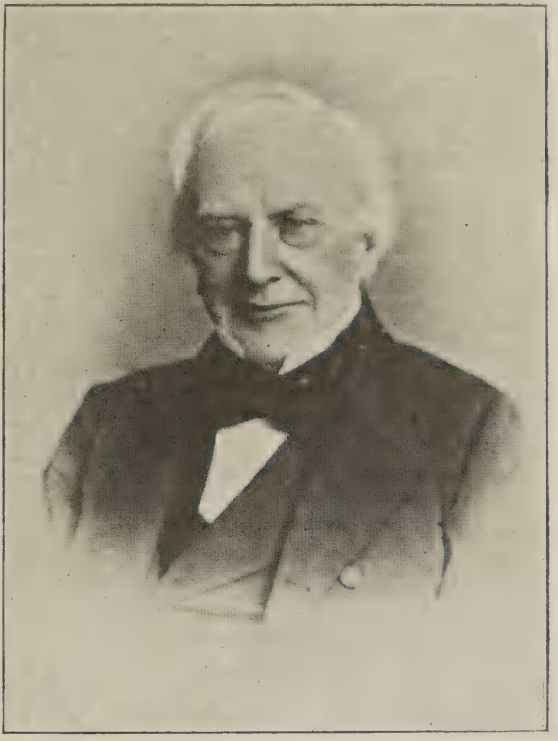

FIG. 8.—SIR WILLIAM LAWRENCE.

Wakley announced the intention of taking advantage of the next Hunterian lecture to convoke a meeting of the Members, in order to compel the espousal of the cause of the Members in general, of naval officers, and of others equally oppressed. Whereupon the Council issued a notice that no public discussions could be allowed in the theatre of the College, and that the doors would not be opened till a few minutes before the delivery of the lecture. Accordingly the doors of the College were not opened till a few minutes before 4 o'clock, when an assembled crowd of Members entered, while simultaneously the President, the Council, and a group of Bow-street officers entered at the other end. Wakley stood up in the body of the hall, and asked who was responsible for the exclusion of the Members from their College till the last moment. A Bow-street officer was sent to order him out; he refused to go, and was supported by the mass of the meeting. The President left the theatre, and Wakley addressed the meeting and moved a vote of censure on the Council for their treatment of the Members. The Secretary of the College re-entered with an order from the President and Council, addressed to Wakley personally, that he should quit the theatre. Wakley refused, and a number of Bow-street officers proceeded to expel him by force. Members ran to his assistance, and after a considerable brawl, Wakley gave a Bow-street officer, who had struck him, into the custody of other officers outside. These refused to take the charge, and Wakley proceeded to Bow-street followed by an increasing crowd, where the magistrate who was sitting stated that he could not grant a warrant. Enormous publicity was given in the newspapers to the whole affair, and a rule in the Court of King's Bench was secured, the gist of which was to make it illegal for the Members to discuss in the theatre of the College any subject not connected with the duties of the Corporation.

The unsatisfactory position thus left endured for some three years, and at this point The Lancet made a bad mistake in policy, and one which had not the endorsement of its best supporters. Wakley proposed to substitute for the Royal College of Surgeons of England a new College of Medicine, which was to have a new Charter, and to do everything as properly as the Royal College of Surgeons of England, in his view and in the view of many vociferous publicists, did everything improperly. It was a socialistic dream, in which all legally qualified practitioners, physicians, surgeons and consultants, apothecaries, general practitioners and consultants, were to be associated on equal terms, and were to ballot annually for their officers, and to conduct examinations on a system of medical juries. The candidates at these examinations were not to be required to produce any certificates whatsoever; capability of passing the examinations would be the only professional qualification for obtaining the diploma.

We all know now that for the profession of medicine, at any rate, the examination test is not a sufficient test of practical knowledge, and that students must follow a prescribed course, and acquire their knowledge at properly equipped centres. But 90 years ago this was not so generally accepted, and there were still those who thought that ability to support a thesis, on the mediæval plan, ought to be sufficient trial for the aspirant. For three years The Lancet carried out what was really an agitation against the Royal College of Surgeons of England under the guise of founding a new College of Medicine, which was, of course, without the elements of existence. Unless the Crown granted a Charter, such an association was useless; unless the State recognised the diplomas of the new body there would be no inducements for candidates to present themselves. A Charter had recently been granted to the Royal College of Surgeons of England, together with money, and against this Charter a petition presented to Parliament had practically failed to effect anything. The House of Commons considered the new scheme the outcome of private ill-will against the officers of the existing College, and at length Wakley acknowledged failure along that line. He had done as much as was possible in his private capacity, and as a journalist he had prejudiced the cause he had at heart by having to own to a complete failure. It remained now for Government to carry on the work that he had commenced, and to carry it on with a far larger scope. The Royal College of Surgeons of England was not the only medical corporation in the kingdom that did not do its duty by its commonalty, and the behaviour of the hospital officials of the metropolis was not the only feature in medical education that needed improvement in the interests of the students. A thorough scheme of reform devised for the good of the public as well as of the profession—in short, a new Medical Act—was wanted, and this could only be carried through with the aid of a party in Parliament. The failure of the London College of Medicine showed Wakley that he must not expect much from any coöperation of the medical profession—in this case a testimony to their good sense—and he resolved to transfer the scene of his struggles from Lincoln's Inn Fields and the columns of The Lancet to Westminster. Just before the accession of Queen Victoria, Wakley headed the poll in a Parliamentary election for the large borough of Finsbury.

MEDICINE AND THE PUBLIC:

Appeal to Public Interests.

During the ten years which are covered between the founding of The Lancet and the first attempt of Wakley to enter Parliament, the pages of the paper had altered in character; success had both broadened the aims and concentrated them. There was no endeavour kept up to diffuse general information, but the universality of medicine in itself, as permeating every circumstance and activity of life, was being discovered. The vitally important questions of the medical practice at the hospitals, of the constitution of the Royal College of Surgeons of England, with special reference to the influence of its by-laws upon the rights of its Members and the education of students, remained as subjects that would be discussed and re-discussed until practical measures of reform were put in hand. But at the same time the first avowed aim of the paper—namely, the dissemination of authoritative medical information, was kept steadily in view. Though a large proportion of the space was taken up by piquant, not to say scurrilous, articles and correspondence, arising out of situations now taking shape as advanced professional politics, the columns devoted to scientific reports were regularly filled with topical contributions from good men. And these undoubtedly benefited in their practices by the appearance of their work in a journal which appealed to a public unusually wide for scientific writers. For The Lancet formed the first popular medium for the interchange of medical thought, while constant openings were given for exercise of that thought.

During these ten years a large and varied number of matters were brought forward in which the public was profoundedly interested, when the medical side was the one dwelt upon. Publicity and a reputation for fearlessness had brought to THE LANCET a heavy mail bag, and the subjects of the administration of the Poor Law, of the Anatomy Acts, of the adulteration or sophistication of food, and of the conduct of coroners' courts were, for example, regularly ventilated.

THE ADVOCACY OF MEDICAL CORONERS.

The attitude taken was professional, and one chief contention in the pages of THE LANCET was that the abuses known to exist in the " Crowner's Quest " would be immediately reduced, or substantially abolished, if the coroner were a medical man. Consequently one of the earliest regular tenets which the readers of THE LANCET were expected to hold was that the office of coroner should be vested in a doctor. The idea was a new one, and to many lawyers, no doubt, also appeared a shocking one, but whether THE LANCET were right or not in insisting that the coroner should possess medical qualifications, thereby implying that under medical coroners all abuses would cease, many writers to THE LANCET had no difficulty in showing that the coroners' courts at the time were rife with abuses. Some of the examples that were printed in THE LANCET during 1828, 1829, and 1830, in illustration of the view that an inquest confided to the supervision of a non-medical coroner presented so many obvious opportunities of error that it ceased to be a public safeguard, are undoubtedly very remarkable. To mention only a few, there is the story of a case of poisoning by prussic acid in which the jury were clearly misdirected. They brought in a verdict of " Suicide during temporary derangement," when there was not only no evidence pointing towards suicide or insanity, but when the possibility of an accident having occurred, and the probability that the accident had occurred through the carelessness of some person other than the deceased, would have been clear to anyone who knew, as the coroner apparently did not know, what was the poisonous dose of prussic acid and what the therapeutic use of this deadly remedy. Another inquest is discussed at some length where a verdict of manslaughter was given against an operating surgeon whose procedure had been perfectly correct, while the fatal injuries which the surgeon was supposed to have caused might have been the natural—that is, pathological—lesions due to the patient's condition, or might, at any rate, have been the natural sequels to such lesions. Only a medical man could have interpreted the medical evidence to the jury in such a way as to ensure justice being done. In a third case a jury brought in a verdict of " Died by the visitation of God and not in consequence of the neglect of any person or persons," where it was perfectly clear to any medical man reading the evidence that the luckless baby, whose death was the subject of the inquiry, had been poisoned by over-dosing with mercury, and had been, in addition, neglected by the medical attendant. The coroner knew nothing of mercurial salivation, the only medical evidence forthcoming was interested, and as a result a miscarriage of justice occurred that would have been impossible if a medical coroner had presided. Another case where the pious but meaningless verdict of " Death by the visitation of God " was given by the jury at the express direction of the coroner, and where all the evidence pointed to the most human agency in the matter, was a wholesale catastrophe due to arsenic poisoning. A family circle having partaken of a particular pie, two died forthwith, a third some 24 hours later, and a fourth was exceedingly sick. The remnants of the pie were thrown into the yard, when some sows ate it, and died there and then. The sequence of events totally escaped the intelligence of the coroner, who obtained from his jury the verdict that his piety desired. The bodies were afterwards exhumed and the cause of death was then found to be arsenic poisoning.

FOOD ADULTERATION.

Adulterations of food were prominently dealt with both in correspondence and in editorial articles. The adulteration of bread with alum, of mustard with barley flour and colouring matters came in for comment, with all their possibilities—as then understood—dependent upon animal tuberculosis and unwholesome meat. In the course of a review the public attitude of THE LANCET towards adulterations of food and drink was laid down in the statement that it would be the duty of the journal never to permit a proved fraud of this description to escape unnoticed, but never to lend the pages of the paper to the creation of epidemic terror by publishing the outcry of every visionary. We shall see that 20 years later THE LANCET, having exactly the same attitude, instituted an inquiry into the abuses of adulteration, under which steps were taken to prove all the charges made.

As with the subject of medical coroners, the medical side was insisted upon in all the editorial articles dealing with food adulteration. But the stated or implied intention to display medicine as a public servant and not as a mysterious councillor in that day of social history was a new idea, and one not altogether grateful to certain practitioners. It was said by the critics of the way in which the paper was being conducted that it was no part of medical men to meddle with the dispensation of the law, their rôle being to await requests for advice. But the closer identification of medical work with social well-being was acclaimed by public men as a valuable departure, such pertinent questions being asked as :—Why should a coroner call a scientific witness when he does not and cannot know that the death is unnatural ? or, How can a dishonest tradesman be convicted if evidence of his guilt, only possessed by scientific men, is not supplied ?

ANATOMICAL STUDY : BODY-SNATCHING AND MURDER.

The legislation in respect of anatomical study formed another topic of frequent debate in the pages of the paper, the balance being held equally between the scientific and social scales. The arduous position of hospital students at the time of the foundation of THE LANCET was aggravated by the difficulty of obtaining bodies for dissection, and the appearance of the resurrectionist followed as a natural consequence of the scarcity of subjects.

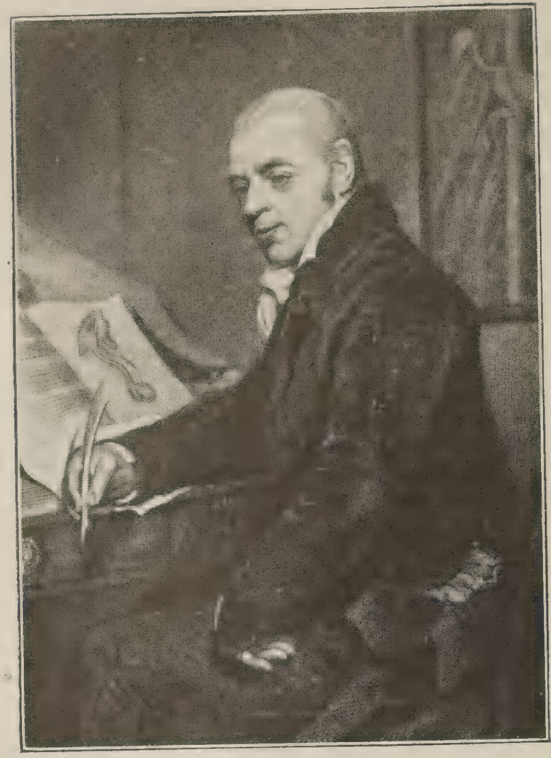

FIG. 9.—JOSHUA BROOKES.

The large sums which had to be paid by students to obtain materials wherefrom to learn practical anatomy, and the poor substitutes of plates and diagrams with which they had too often to be contented, were blots on the system of medical education, while rifled churchyards constituted a grave scandal. Suddenly a tremendous element of terror was introduced into the situation by the tragedies in Edinburgh with which the names of Burke and Hare are associated in infamy. The facts of the tragedies are too well known to call for a detailed description, and were set out with far more detail in the lay press than in THE LANCET. Suffice it to say that these two men were, during the years 1827 and 1828, engaged in carrying on a ghastly traffic in human bodies, their plan being to induce strangers, lads or women, to accept the shelter of their roof, when, being stupefied by strong drink, they were smothered and their bodies sold to certain Edinburgh surgeons for dissection. Hare gave Queen's evidence and so incriminated Burke as to lead to a sentence of death being passed, when Burke made a confession, admitting his guilty knowledge of murders extending over quite a long period.

A Parliamentary Committee was appointed in response to such revelations; without them it may be feared that the warnings of medical journalism would have gone unheeded. The reference of the Committee was to inquire into the state of anatomy as practised in the United Kingdom, and on this Committee Henry Warburton, whose name should always be remembered in the medical profession as an untiring champion of its true interests in Parliament, was appointed chairman. Among the witnesses were Astley Cooper, Brodie, Abernethy, and Joshua Brookes (Fig. 9), the greatest anatomist of the day and head of the largest private medical school in the metropolis. The evidence of the first and last of these proved that as far as London was concerned the teachers of anatomy were at the feet of the resurrectionists. Wakley was called as a witness in recognition of the numerous articles published in THE LANCET dealing with the inadequacy of medical education of the day, which was allowed to have led up to body-snatching and now was seen to put a premium upon murder. He began characteristically with a criticism of the Royal College of Surgeons of England, pointing out that the Council of the College had drawn up a by-law refusing to accept certificates of dissection except for work that had been performed in the winter season. The obvious effect of this was, he said, to increase the demand for subjects at that season and to raise the price. He considered the dissecting rooms during the winter to be much overcrowded with students and under-supplied with bodies, and laid the whole blame on the objectionable by-law of the College, which limited the number of recognised institutions to the detriment of the private schools. He repeated the counsel given in THE LANCET to obtain the coöperation of parochial authorities, showing that 700 bodies per annum would be ample to supply

FIG. 10.—RICHARD PARTRIDGE AND GARIBALDI

the needs of London, and that more than one thousand unclaimed bodies were buried by parish authorities in the metropolis yearly. The suggestions made by the journal were accepted by the Committee.

Warburton accordingly introduced a Bill, the gist of which was that bodies of men and women who died in workhouses or hospitals without being claimed within a certain time of death should be sold for dissection. This Bill was not clear about licensing anatomy schools, nor did it provide for Christian burial of the remains after dissection, but with modifications in these directions it passed the Commons. In the Upper House it was opposed by a group of peers headed by the Archbishop of Canterbury and withdrawn, when a new tragedy—this time in London—called attention to the absolute necessity for the legal regulation of the study of anatomy. An Italian boy, who made his living by exhibiting tame mice in the streets, was enticed by two ruffians to a den in Bethnal Green, where he was murdered and thrust down a well. The murderers with an accomplice set out to dispose of the body, but suspicious circumstances attracted the attention of Mr. Richard Partridge, the demonstrator of anatomy at King's College, to whom it was offered, and the murder came to light. The men were convicted and executed and the Anatomy Act of 1832 was immediately passed. The illustration (Fig. 10) is from a painting in the possession of the Royal College of Surgeons of England, and shows Partridge in attendance upon the illustrious Garibaldi.

MEDICINE IN PARLIAMENT.

THE primary intention of Wakley to enter Parliament was due to the defeat in Parliament of measures for the reform of the medical profession which he considered to be the result of the absence from the legislature of persons who knew the facts. But this intention gathered force from the discovery in so many different places of public abuses where the services of medicine could be employed in remedy or mitigation. And he was confirmed in his resolution by finding that the medical profession drew warmly to his side as week after week subjects of grave general interest were debated with the proper emphasis laid upon the medical aspects. Accordingly he decided to stand at the first general election after the great Reform Bill for the newly constituted borough of Finsbury.

THOMAS WAKLEY AS PUBLIC MAN.

At this point the story of THE LANCET becomes again very much the story of its founder. In 1831 the borough of Finsbury came into existence and Wakley was now resident in Bedford-square, situated almost in the centre of the enormous new constituency, estimated at 330,000 voters. It included six large parishes, five "liberties," Lincoln's Inn, Gray's Inn, and those parts of the parishes of St. Sepulchre and St. Andrew's, Holborn, and of Furnival's Inn and Staple Inn respectively, which were without the Liberty of the City of London.

Wakley had become favourably known to many neighbours. His treatment of public affairs in THE LANCET commended itself to progressives, and his speeches on parochial and municipal matters were business-like. He was able to support his views not only in THE LANCET, but by valuable assistance from friends in the lay press. His desire, therefore, to transfer his work for placing the status of the medical profession upon a sounder foundation to the House of Commons was singularly well met when an important group of Finsbury electors invited him to become their representative. Over and over again, in war against the constitutional authorities of the professional world, in conflicts with the Royal College of Surgeons of England, and in attempts to break down the barriers of secrecy erected by the administrators of the hospitals, he had felt the need for a strong voice within Parliament. He desired to represent the interests of his profession in Parliament and to press there for reform in medical politics, and he desired also to initiate or take part in departures for the sanitary improvement and physical and moral well-being of the population, whose necessity he had been showing week by week. He was not trying to be a Member for Medicine, but, quite literally, a Member for THE LANCET, as certain public causes were being epitomised and championed in its pages. He saw, as we are seeing to-day, that a period of popular unrest would bring into the House of Commons the legitimate discussion of many medical questions, but though his own aim in desiring to enter the House was to further the cause of medical reform and be an expert witness ready to hand whenever points arose in the deliberations of the House where experience in medical matters would be serviceable, he conformed to the views expressed in THE LANCET that no such electoral cry as "justice for doctors" ought to secure him a seat. He came forward for Finsbury at the first election after the Reform Bill as an advocate of advanced reform principles, as a supporter of all claims for the amelioration of the condition of the people, and in particular as the enemy of Protectionist tariffs on the nation's daily food—a sort of general Radical programme infused with medical knowledge. He was not immediately successful, taking only fourth place among five candidates at the first election which he contested. This was at the end of 1832. Some 18 months later one of the sitting Members became Governor of Bombay, when Wakley contested the seat at the by-election. His decision to do so was made suddenly and his figures which were growing significant, represented only one day's votes. Seven months later a general election followed, when at the third attempt he was duly elected, turning out one of the sitting Members.

THOMAS WAKLEY, M.P.

The first occasion on which Wakley used his seat in Parliament to advance the medical profession was during the debates on a County Coroners Bill, and that occasion showed very well the political power which in those times it was possible for a medical paper to exercise. Many of the actual situations dealt with in the County Coroners Bill had been stated for years in THE LANCET, and when at last the Bill was presented to Parliament it was rejected by a House doubly enlightened, first by Wakley's speeches and writings, secondly by articles which had received wide notice and had been reprinted from THE LANCET, and thirdly by a report on medical education which had been presented to the House about the same time. The Bill, as it stood, did no justice to doctors ; their help, where sought, was not to be rewarded. This report came directly from the columns of THE LANCET, and was an attempt to find a constitutional remedy for the many undoubted abuses that were rife in medical training.

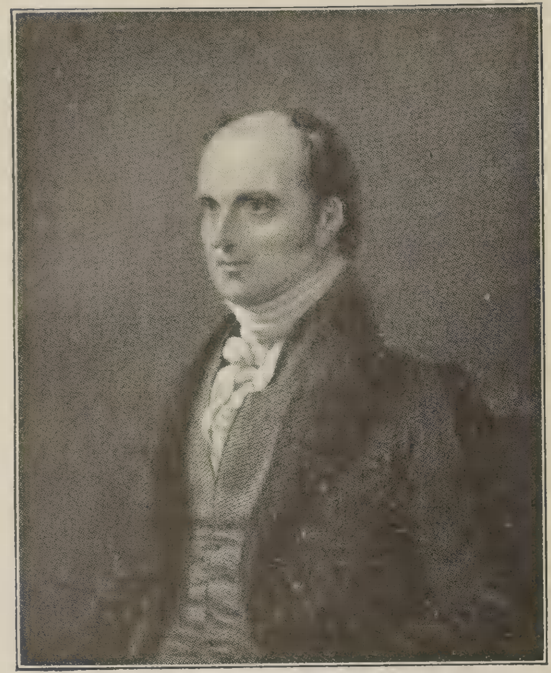

FIG. 11.—HENRY WARBURTON.

Henry Warburton (Fig. 11) an Etonian, a wrangler, and a merchant, was a considerable figure in the House, and may be regarded as a representative philosophical radical. He had moved for a Committee of Inquiry on the subject, when Wakley had not a seat in the House, but without THE LANCET the unanimous agreement of Parliament would not have been obtained for its appointment. It was THE LANCET's ever-recurring and ever-varying revelations of the anomalies present in the system of medical education, persisted in for over a decade, uncontroverted and practically uncontrovertible, which finally bore fruit. In fact, Warburton's Committee was the result of the agitation in THE LANCET, which was supported manfully from without by the public press. The exclusiveness of the Royal College of Physicians of London, the tyranny of the Royal College of Surgeons of England, the pettifogging tactics of the Society of Apothecaries, these were weekly themes, and not bad samples of the weekly phraseology, and so pungently were they treated and with such disregard for the position or importance of the figure-heads in the various corporations, that everyone read the articles. They possessed the piquancy of their insolence and compelled attention from those quite innocent of any desire to see justice done to the medical profession. So that when Warburton asked the House to appoint the Committee, he appealed to an alert assembly wherein there was already a general feeling that some such inquiry ought to be made. He obtained what he wanted immediately. Wakley was personally responsible for Warburton's Committee, inasmuch as it was he who showed Warburton how to secure the evidence and what to look for.

THE GERM OF MEDICAL REGISTRATION.

THE LANCET had dissected the charters of all three of the London corporations, and had indicated what each body could do by law and what each body could not do by law, as well as what each body had taken upon itself to do by custom. Wakley knew where the law had been evaded, where it had been broken, and where it had been stretched, and in all those practices he knew when the result bore hardly upon the student and on the working of medical education. All this knowledge he placed unreservedly at Warburton's disposal, and its possession enabled that reformer to act with confidence and to steer his Committee with discretion.

The rulers in medicine were the men who had acquired a recognised university degree and, subsequently to graduating, had been elected to the Fellowship of the Royal College of Physicians of London. The Charter of this body was granted by Henry VIII. for the advancement of medical

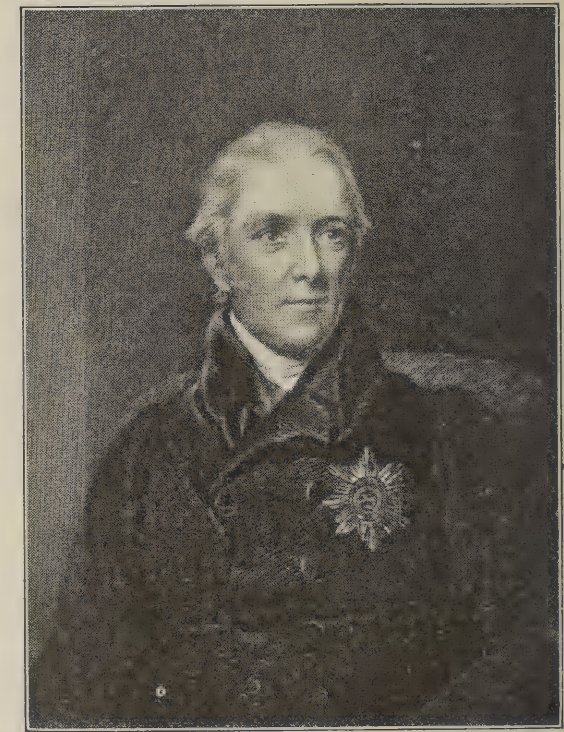

FIG. 12.—SIR HENRY HALFORD.

science and for the protection of the public "against the temerity of wicked men and practice of the ignorant," but time had imported into it restrictions and disabilities uncontemplated by the monarch or his advisers. The College was divided into Fellows, Members and Licentiates. The Licentiates paid fees to obtain a licence to practise within seven miles of the metropolis, but the College had little or no power to maintain the sad monopoly thus sold to them. The Fellows, frequently chosen it would seem with disregard for professional merit, had passed regulations for keeping their body select which were recognised by all as obsolete. No physician could be admitted as a Fellow unless he had graduated at Oxford or Cambridge, or had been admitted to a degree *ad eundem* at one or other of the ancient universities. This restriction carried another with it, for the graduates of Oxford and Cambridge were obliged at that time to be members of the Established Church of England, whence it followed that no dissenter could be a Fellow of the College of Physicians. The College also recognised for purposes of Fellowship those gentlemen who were privileged to call themselves doctors of medicine by direct licence from the Archbishop of Canterbury—M.D. Lambeth, and always called in THE LANCET "Divine Doctors." This was a very small class indeed, but it happened that at this very date one of them was the well-known obstetric physician, Sir Charles Mansfield Clarke. In 1823 the College consisted of 88 Fellows and 216 Members, and certain licensees, and, as will be seen from the figures, did not play a sufficient part in general medical politics to come much under the notice of medical journalism. The references to it in THE LANCET chiefly take the form of criticism of the courtier and physician, Sir Henry Halford, who occupied the Presidential Chair for 42 years (Fig. 12).

The position of affairs in the Royal College of Surgeons of England has been sufficiently indicated by the description of the agitation against its constitution, but it should be pointed out that the practice of midwifery and the dispensing of drugs were considered by the authorities of the College to mark the difference between the "pure surgeon"—to use the phraseology of the day—and the general practitioner. Out of this situation had arisen the Apothecaries Act of 1815, by which the Licentiate of the Society of Apothecaries obtained a definite position as a practitioner of medicine, while his governing body claimed for him a monopoly in dispensing. The Apothecaries Act had as its laudable object the prevention of prescribing and dispensing by unqualified persons, and secured its passage as a measure for the restriction of quackery, but it created incidentally a class of practitioner which could not easily be moved to call for reform. The Act, combined with the apathy of the Royal Colleges in the matter, led to the situation that many members of the medical profession in London and the provinces made no attempt to gain any other diploma than the L.S.A., and consequently were not personally interested in the great plans for reform which were just beginning to take definite shape.

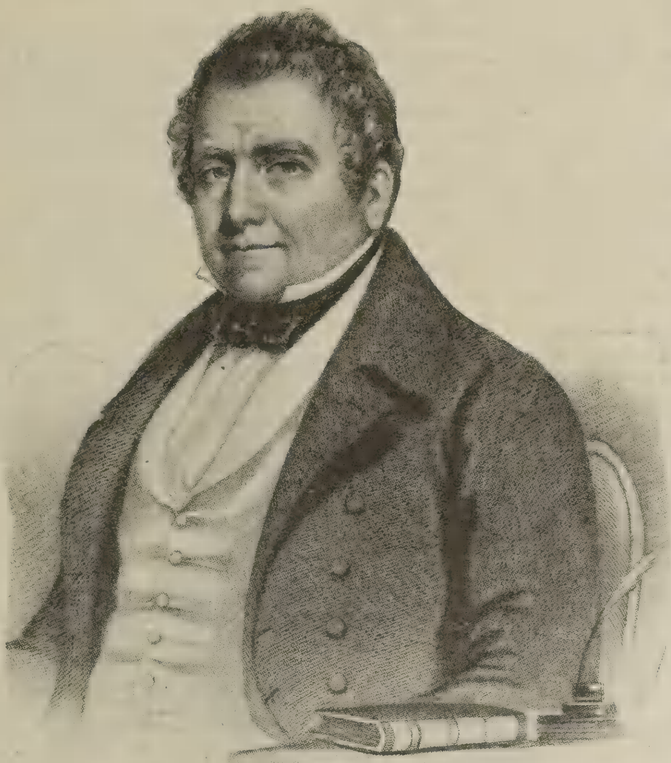

FIG. 13.—JOSEPH HUME.

WARBURTON'S FAMOUS COMMITTEE.

When in 1834 Warburton moved for his Parliamentary Committee of Inquiry into the state of the medical profession, Joseph Hume supported him, holding up to ridicule the anomalies of the Apothecaries Act as affording proof of the necessity for someone to be present in Parliament to interpret medical matters to the legislature. The motion was agreed to without a division and an exceptionally strong committee was appointed. Warburton was chairman and was supported by, among others, Lord Howick (eldest son of Earl Grey, the Prime Minister and introducer of the Reform Bill), Mr. J. Abercromby (elected Speaker of the House of Commons in the following year), Mr. Halford (son of Sir Henry Halford, the long-established President of the Royal College of Physicians of London), Daniel O'Connell, Mr. Spring Rice (afterwards Chancellor of the Exchequer and Lord Monteagle), Joseph Hume, Lord Oxmantown (afterwards Earl of Rosse of telescope fame), and Sir Robert Peel.

Joseph Hume (Fig. 13), a political power in the House of Commons almost since his election for Weymouth in 1812, was later and for many years Member for Aberdeen, then one of the Members for Middlesex, and at the time of his death in 1855 was Member for Montrose. He was the oldest of a remarkable group of political reformers. He was the mover of the repeal of the corn laws, and an authority on all subjects of public expenditure. His deep interest in medical questions was due to the fact that he was educated as a medical man and entered professional life as a surgeon in the service of the East India Company. His rapid acquisition of languages and his organising qualities led to his appointment to important posts in India, so that he was able to return to England while still a young man with a considerable competency as well as a high reputation. If Wakley drafted the first Bill for the reform of the medical profession, it would not have received the immediate attention that it did, had it not been supported by men like Henry Warburton and Joseph Hume.

The Committee was appointed to take evidence on the following important and diverse subjects: Treatment of parochial poor; farming of sick poor; treatment in institutions supported by voluntary, life, and annual subscriptions; mode of appointing officers of such; appointments to gaols, asylums, and similar institutions; regulations of private lunatic asylums; the proper qualifications for masters in lunacy; the state of medical practice generally and its supposed effect on the public health; the practices of unqualified persons and quacks as regards public health and reputation of the profession; the public sale of secret remedies; the revenues of endowed institutions and the numbers of patients treated in them and the state of those patients; the mode of appointment of Navy and Army medical officers; the number of students attached to "chartered" hospitals and fees paid by them; the qualifications and legal rights of Fellows and Licentiates of the Royal College of Physicians and Members of the Royal College of Surgeons and of Licentiates of the Apothecaries' Company, the fees charged at the foregoing institutions and the manner in which such funds were appropriated; the system of medical apprenticeship; the status of chemists in regard to dispensing; the actual amount of wealth in possession of each of the chartered medical institutions; and the appointment of medical professors and court examiners at both the corporations and the universities.

The following were among some of the witnesses called: Cæsar Hawkins, Sir Henry Halford, James Copland, editor of *The London Medical Repository*, John Elliotson, the famous physician, later so damaged by dabbling in mesmerism, James Johnson, editor of the *Medico-Chirurgical Review*, and J. G. Guthrie (Fig. 14), three times President of the Royal College of Surgeons of England, Sir Astley Cooper, Sir Charles Bell, the famous anatomist and lecturer at the Great Windmill-street School, James Wardrop, Benjamin Travers, Benjamin Brodie, Richard Grainger, Joseph Carpue, William Lawrence, and Joseph Henry Green. The Apothecaries Company sent six special witnesses, and most of the private teachers, as well as Carpue and Grainger, had an opportunity of addressing the Committee. Prof. Macartney came from Dublin, William Hey, junior, of Leeds, and John Green Crosse, of Norwich, represented provincial surgery worthily, Profs. Christison, Allison, Abercromby, Poole Thomson, and Maclagan were present from Edinburgh. Glasgow, Aberdeen, and St. Andrews also sent witnesses.

All the evidence of these experts was printed in THE LANCET, explained and copiously annotated, so that both the House and the medical profession had a chance of learning the real need that existed for reform, not only from persons interested in altering the existent and corrupt state of affairs, but out of the mouths of those very heads of the profession whose rule had been so bitterly attacked by THE LANCET and whose rejoinder had been an invariable and stiff-necked assertion that things were very well as they were, and that the disaffected persons were either malicious malcontents striving to be important or their hoodwinked followers.

Wakley for ten years had made certain statements in THE LANCET. Now was the hour of his triumph, for witness after witness willingly or unwillingly confirmed these statements and made it clear to the country that medical reform was really required upon the very lines indicated by the journal which was by solemn agreement on the part of the London surgeons and teachers condemned as hopelessly wrong-headed and prejudiced. The country during the sitting of this Committee was no longer listening to THE LANCET, but to all sorts and conditions of expert testimony to the accuracy of the paper. Guthrie, for example, speaking on behalf of the Royal College of Surgeons, of which body he had been elected President for the first time in 1833, said that he considered the process by which the 20 existing members of the Council, or governing body, elected the twenty-first man to their body was an absurd plan, and that any other would be most acceptable. Immediately afterwards he added that no other plan would be satisfactory. He thought that surgeons should not dispense their medicine or practise midwifery, as anyone who gave time to such trivialities would have none left in which to acquire the principles of "pure" surgery; but he admitted that while only the non-dispensers could be chosen on the Council the power would be absolutely in the hands of 200 "pure" surgeons to govern 8000 persons, presumably as well educated as themselves—viz., the Members. He defended the system by which the ten senior men of the 21 councillors were examiners in spite of the fact that councillors were chosen for life, and that some of the senior men would therefore presumably be past their work. And he spoke well of the high rate of fees exacted from the London student. His evidence was printed at length in THE LANCET, much to his disgust, and proved in the clearest possible way that THE LANCET had not exaggerated during the past ten years when it described the Council of the College as "a self-perpetuating junto" and its educational scheme as useless, giving as the reasons, first, that pharmacy and midwifery were not included in it, and secondly, that the examiners were not fit and proper persons. If these facts had been elicited before the Committee from Scottish or Irish teachers, jealous of certain of the advantages enjoyed by the London corporations, or if they had been insinuated by Grainger and Carpue, sore at the greedy opposition offered by the College professors to all private tutorial enterprise, or if they had been advanced by Wakley himself, a known foe to the English College, the public might have looked with suspicion on the evidence as tainted. But Guthrie was speaking for the College—as the President of the College, in fact—in favour of keeping things as they were, and he satisfactorily convinced the Committee of the urgent need of reform.

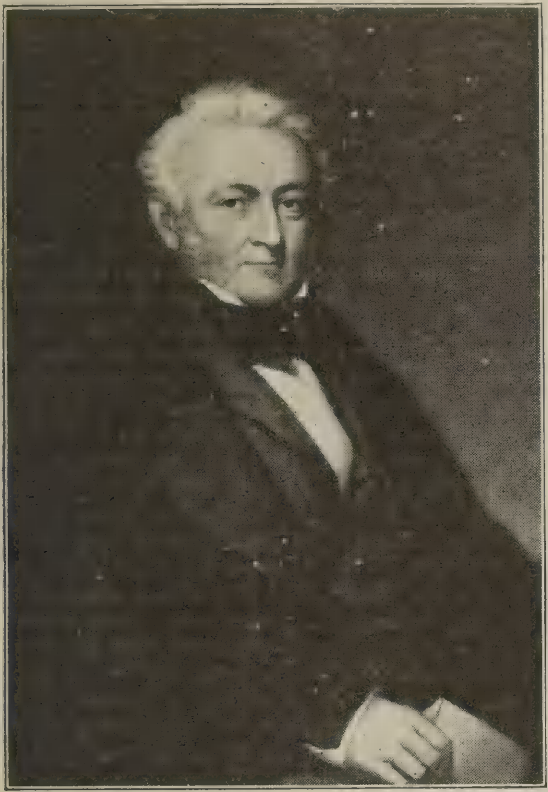

FIG. 14.—J. G. GUTHRIE.

It has been necessary to go back in the story to explain how useful the revelations in THE LANCET had been to the House of Commons. It was in a House in full possession of such evidence as this, taken before a Parliamentary Committee, that Wakley criticised Mr. Cripps's County Coroners Bill from a medical aspect. The House was prepared to believe that in matters of medical reform the honourable Member knew what he was talking about. He was listened to with attention and secured the approval of his fellow legislators for several amendments, chief among which was that the medical witness should be treated as an expert and should be paid at inquests one guinea for his attendance and another for making a post-mortem examination if directed to do so by the court. The Bill was afterwards rejected as a whole, but Wakley's prompt and successful employment of the first opportunity that had presented itself to him to watch over the interests of the medical profession in Parliament did not go without recognition at the time, while it led to practical results in the immediate future. He was publicly thanked by several medical associations. He was also begged to renew his endeavours in the next session of Parliament to obtain adequate remuneration for medical witnesses in the coroners' courts. Three months later the Bill became law.

The work of THE LANCET was now bearing fruit. Some of the abuses revealed in every direction were being met, and the feeling was growing that a general measure of reform was called for.

THE FIRST MEDICAL REFORM BILL.

In 1846 Wakley, having been elected for the fourth time Member of Parliament for Finsbury, brought in a Bill for amending the law relating to the practice of medicine in Great Britain and Ireland, founded on his experience gained as an editor. He had collected round him first all the men who had grievances in the profession, then a group of publicists who saw in those grievances a reflection of much in general affairs that constituted abuses, and lastly, many leaders of the medical profession who were convinced, sometimes unwillingly, of the need for reform. This Bill was Wakley's greatest Parliamentary work, and its indirect results to the medical profession were of incalculable good. Direct results it had not, for it never became law, but it led to the appointment of a select committee of sound, shrewd, important men whose deliberations resulted in the Medical Act of 1858. That Act fell short of the ideals put forward by many writers in THE LANCET, and endorsed by editorial views in the paper; but while it may be admitted that those views were more than occasionally visionary, and would certainly have much impeded the course of legislation by the opposition with which they would have been met, it may be recalled that future amendments of the 1858 Act have turned some of them into law.

Wakley's Bill was short and exceedingly clear, and the gist of it was to ensure that there should be accurate registration of the whole profession with strong penal powers capable of being set in motion against pretenders. It was, in fact, a Bill against quacks, but it was a measure for the protection of the public, and not for conferring undue privileges upon medical practitioners. It provided for the appointment of a registrar for each of the three divisions of the United Kingdom. It specified that his duties were to make, within 30 days of the passing of the Act, a list of all the properly qualified members of the medical profession resident in his division of the United Kingdom, whether by degree, diploma, certificate, or licence, and to these lists there were to be added, as fit subjects for registration, all persons who had been in actual practice as apothecaries since 1815 and all surgeons and assistant surgeons of the Navy, Army, or Honourable East India Company. In accordance with such official lists, which were to be entitled the Medical Registers for England, Scotland, and Ireland, respectively, certificates were to be issued annually to all the names included at a fee of 5*s*. It may be noted that some 50 years later, when the pecuniary position of the General Medical Council was the subject of some anxiety, exactly this way of obtaining an annual income was proposed. Every person, thus duly registered, was to be entitled to practise in that division of the United Kingdom where his certificate was issued, and to charge for visits and attendance, and to recover such charges, as far as they were reasonable, in any court of law. He was to be exempt from serving on juries. None but registered medical practitioners were to be so privileged, and clauses were provided for the summary punishment of unregistered practitioners, whether detected practising without a qualification or with a qualification obtained by irregular means, while it was also made penal falsely to pretend to possess a qualification. The recovery of the penalties was simple and swift. The purification of the register—that is to say, the honour of the profession—was to be left in the hands of the various universities or corporations whose graduates or diplomates composed the profession. The three registrars were merely bound to register persons who possessed certain qualifications and who complied with the regulations by proving their ownership of the same and paying their fees. A name once on the register could only be removed by the authorisation of the body from which its owner derived qualification. The professional crimes which, if proved, warranted such authorisation were specified as "conduct calculated to bring scandal and odium on the profession by publishing indecent advertisements or pamphlets or immoral or obscene prints or books, . . . or any other disgraceful and unprofessional behaviour." The names of the convicted could be erased by the registrars. It will be seen that the penal clauses were open to the curious criticism that they proposed to confer on the very bodies whose irresponsibility to their constituencies were in question arbitrary power of a terrible sort. Wakley and others by name, and all the editorial staff of THE LANCET by implication, had been accused of bringing odium on the medical profession and of using indecent language. Many of them were in the Editor's case of deriving their professional status from the body most bitterly attacked. The Council of the Royal College of Surgeons of England, under Wakley's Bill, could have degraded these men, apparently with no power of appeal, to the position of quacks.

With regard to medical education, Wakley saw that a Bill which proposed "to distinguish between legally qualified physicians, surgeons, and apothecaries and mere pretenders to a knowledge of medicine and surgery," as the preamble bluntly put it, must enact that proper tests should be applied to candidates for a position on the register, lest the distinction between those included in and those excluded from the official lists should be one without a difference. After repealing the enactment establishing apprenticeship to an apothecary as an educational curriculum, the Bill set out a scheme of uniformity of education, qualification, and fees throughout the Kingdom. No details were suggested, the proposer knowing that the various views of the numerous bodies granting medical qualifications would have to be heard on the subject; but the principle of one portal to the medical profession, by which all practitioners were placed upon the same level at the commencement of their careers, was strongly insisted upon. In many future discussions on medical education the simplicity of the scheme of a State examination has won adherents for it, but the difficulties that would be introduced by its adoption have now become generally apparent.

THE LANCET scheme for medical reform led to the Act under which the General Council of Medical Education and Registration was created, and Wakley's efforts to raise the status of the medical profession in THE LANCET were during the intervening period devoted to the support of the principles laid down in his Bill. The majority of medical men, especially the better class of practitioners, saw in the measure an immense raising of their standard, but those of the consulting class were not ready with their support. They were not pressed upon by the unfair competition of quackery to anything like the same extent, and it was felt that their support would have been wanting at the critical moment. Anyhow, in spite of the popularity of the measure with the class whom it was designed to benefit, the Bill was not adopted by the Government, and Wakley accepted the suggestion that a Select Committee of the House should inquire into the subject.

Wakley's Parliamentary activities, it can be understood, helped both his work in Parliament and the profession of medicine, while the information supplied by the medical profession to THE LANCET helped him and his colleagues alike. But while the pages of the paper were thus fiercely political it would have availed Wakley little if he had not been at the same time publishing first-class scientific material. Neither natural zest for sensation nor abundant sympathy with the reforming spirit would have made THE LANCET a general success with the profession if the educational side of the paper had been neglected. Consultation of the issues of the journal during these years, up till 1850 or so, show how steadily the intention was maintained to advance the knowledge of medicine by publishing every week the best sort of medical information while abating nothing in the vigour of political articles, and, at any rate till the close of the indicated period, abating but little in the personal acrimony of the dialectics.

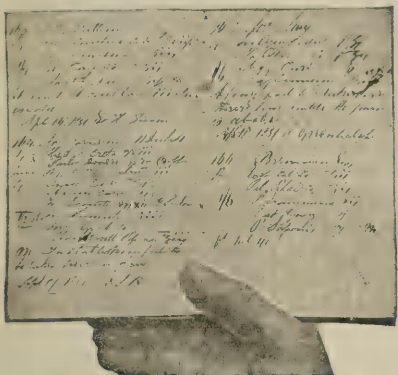
In support of the statement that the pages of the paper supplied the medical practitioners of the day with the latest scientific information, we may mention examples, sometimes sought for in the indices but far more often hit upon by chance or chosen at random, of outstanding communications dealing with the scientific side of medicine and with important relations between medicine and the public.

THE HOVSE *of* MARTINDALE

A FEW REMINISCENCES

Fifty Years of Progreſs—1873-1923

No, there was no need to advertiſe in thoſe days. The work was doubtleſs ſufficient for the day, and for the "apothecary" of the times. Nowadays the work is poſſibly a thouſand times as great, but one wants more work—hence this advertiſement.



Here is a little note book, meaſuring ſome eight inches by four inches. The title page, written in an old-faſhioned hand-writing, indicates "Preſcription Book, 1850, Nos. 1-500." One handles the little tome with a degree of reverence. It was ſtarted by our predeceſſors. There is a pencil note, "W.M. entered May 23rd, 1873." Then began, if we may ſay ſo, a buſineſs now known throughout the world; a Houſe always following the trend of ſcientific medical treatment. It would be impoſſible adequately to review its growth in theſe few brief remarks.

We are not in the habit of boaſting, but we ſay in all ſincerity, that there has not been an important drug or chemical, or a method of treatment, attracting any attention during the laſt half-century, with which the Houſe of Martindale has not been in ſome meaſure connected.

Cocaine

Cocaine, a "bête noire" of the medical man to-day, was introduced to the Medical Profeſſion by the late W. Martindale. The little book, "Coca and Cocaine," is a claſſic. To dip into its pages is to realize the importance of the diſcovery and to recall that even the relatively unciviliſed Mexican Indians, in all probability, have never uſed Coca for hideous malpractices: they uſe it for its marvellous ſtaying-powers, and "civiliſed" ſuperman of to-day is the evil-doer who has brought this, one might ſay divine, drug into evil aſſociations.

Jaborandi

It is perhaps not known to the reader that the powerful ſudorific properties of Jaborandi were the ſubject of inveſtigation by the founder of this buſineſs. He nearly loſt his life while determining the doſe and activity of the drug. Sidney Ringer pulled him through.

Voſodilators

A Fenian Outrage!

It is in the field of the vaſodilators, notably under the guidance of Sir Lauder Brunton, that much early reſearch work of the Houſe of Martindale, was conducted. There is the tale of a young German, who was in our laboratories prior to the war. He came over to learn (amongſt other things!) the language. The far-famed "N.G. Tablets *Martindale*" were in proceſs of manufacture; the young man picked up and ate a piece of the chocolate "maſs" (1/100 grain of Nitroglycerin in $2\frac{1}{2}$ grains) the ſize of his thumb, thinking it to be merely ſweetmeat. He was quickly informed by the manager of the laboratory of his miſtake. He danced round the laboratory, ſhouting, "Ach mein Gott! Ich ſterbe!!"—perhaps he did later! The vaſodilator effect of the exploſive was ſufficiently tranſient to allay immediate qualms. Nitroglycerin, in tablet form, through the auſpices of the parent pharmaciſt, had been made official in the Britiſh Pharmacopœia in 1885.

Boric Acid Ointment

Going back to the old days, our ſtory would not be complete without mentioning that hallowed name, Liſter. Few, perhaps, are aware that the houſehold remedy, Boric Acid Ointment, was deviſed by W. Martindale, at 10, New Cavendiſh Street, for Lord Liſter, the greateſt human benefactor of mankind.

Cyanide Gauze

Again, apart from thiſ relatively weak antiſeptic, W. Martindale ſuggeſted to Lord Liſter the uſe of Mercuro-Zinc Cyanide to impregnate gauze, and "Cyanide Gauze" became known all over the world.

Amyl Nitrite Sterules

The idea of ſealing that volatile remedy, Amyl Nitrite, into "Sterules" was another of thoſe brilliant inſpirations of the man who laid the foundation of this buſineſs. Amyl Nitrite "Sterules" have probably ſaved countleſs lives. We have examined Amyl Nitrite contained in a "Sterule" twenty years after its manufacture and have found it to be of almoſt its original ſtrength and purity. Amyl Nitrite "Sterules" are exported to every foreign country.

It may be 'à propos' to dwell briefly on more recent times.

Radium

The firm took an active intereſt in the therapeutic uſe of Radium from the earlieſt account of its diſcovery. We ſupplied the firſt tubes of Radium Bromide to a well-known X-Ray ſpecialiſt for medical uſe. The moſt diverſe forms of applicators have been produced from time to time.

Organic Arſenic

An elaborate paper on experiments and original reſearch was communicated to the International Congreſs of Applied Chemiſtry, in London in 1909, bringing knowledge up to the Arſenobenzol period.

Lactic Acid Bacilli

A well-known therapeutiſt and ſpecialiſt in tropical diſeaſes walked into the pharmacy in 1907 and aſked us to procure a ſupply of Profeſſor Metchnikoff's remedy. He was the firſt here to uſe the Lactic Acid Bacillus to combat abnormal putrefactive bacteria in the inteſtines; it was not long before the firm produced "Trilactine."

Synthetic Chemicals and the War

The war altered the aſpect of many things in the realm of organic chemiſtry. There dawned the poſſibility of manufacturing organic chemicals, previouſly made in Germany, at a profit, or, at leaſt, to do ſo as a matter of patriotiſm. The preſent writer, with the help of other Engliſhmen, worked out details of manufacturing proceſſes. Information acquired was given freely to ſcientific workers and, indeed, to our competitors. *En paſſant*, the pure humbug of certain German patent ſpecifications was brought to light.

We could go on telling the tale of "No. 10" by the hour. Many were the urgent orders that were executed in thoſe dark unprepared days eight or nine years ago.

Urgent Orders

A ſcientific worker wanted 8,000 broth tubes filled in a day. It could be done and was done. We ſent to the timber merchants for the wood, and to the galvanized metal people for gauze to make the crates to hold the tubes during the ſterilizing proceſs. The order was executed in the time at our diſpoſal, giving an average of 1,000 tubes an hour!

Aſpirinates

Aſpirin was firſt uſed medicinally in 1899. The value of its advantage over the exiſting Salicylates showed that Aſpirin was a drug that had *come to ſtay!* And yet it could be improved upon. The firm ſtarted to make ſoluble ſalts of Aſpirin. The ſequence, Tylcalſin→Tyllithin→Tylnatrin→Magiſal, was a natural one to thoſe intereſted in the pharmacology of drugs.

Can Aſpirin be given intravenouſly? No, but Tylcalſin and Tylnatrin can, and have been, with ſucceſs. They are direct bactericides for combating rheumatic affections. Is it not probable that the intravenous uſe of drugs will be *the* method of adminiſtration of the future?

Sedaſprin and Aſpriodine

Within the laſt few months the proceſſes of manufacture of Sedaſprin and Aſpriodine have been worked out at N.C.S. They contain as *definite ſtable* compounds, reſpectively, 30·86 per cent. Bromine and 41·47 per cent. Iodine. The reſt, in each inſtance, is Aſpirin. The value of the combination of the active halogens is clear to the pharmacologiſt. They are neither of them affected by phyſiological acid and they are ſplit up by the alkalinity of the digeſtive tract. We have another member of the Aſpirin ſequence "on the ſtocks"—of this more anon.

Emetine Periodide

Emetine Biſmuth Iodide was ſhown by us to have been advocated on an entirely erroneous theory. It *diſſolves* in phyſiological acid—hence the nauſea it produces, and the fact that it is in general badly tolerated. We worked out Emetine Periodide, $C_{29}H_{40}N_2O_46I$, a ſtable body, containing 38·7 per cent. Emetine and 61·3 per cent. Iodine. It was highly ſpoken of by the author of an important paper on amoebic dyſentery, read before the Royal Society of Tropical Medicine and Hygiene, in London, in May laſt. "Emetine Periodide was by far the moſt effective, and, at the ſame time, the leaſt toxic of all the Emetine preparations tried."

And of Chaulmoogrates, Colloidal Metals, Strawberry Vitamines, Peptone for immunization in bronchial aſthma, Pituitary preparations, Quinidine, Thyroid Standardized—much might be ſaid if ſpace permitted.

We will conclude with the ſmall conſolation:

"MULTUM ADHUC RESTAT OPERIS, MULTUMQUE RESTABIT, NEC ULLI NATO, POST MILLE SÆCULA PRECLUDETUR OCCASIO ALIQUID ADJICIENDI."—*Seneca.*

EIGHTY YEARS AGO.

EARLY CLINICAL COMMUNICATIONS.

THUS we find, ranging these comments roughly in chronological order, clinical lectures by Elliotson, Henry Earle, Charles Bell, Thomas Watson, and notably lectures on medical jurisprudence by John Gordon Smith, which were followed by a series of practical commentaries on Christison's processes for detecting poisons. All these men were prominent at the time, and some of them contributed in the manner indicated by their writings to the permanent advancement of medical science. Elliotson (Fig. 15), physician to University College Hospital, and the dedicatee of "Pendennis," fell into disrepute later, because of his hankering after mysticism, but he was a famous clinician, and erred only by excess of imagination and a certain impatience of the obvious. Henry Earle, nicknamed by Wakley and his followers the Cock-sparrow, was an enlightened and progressive surgeon, and later a very good President of the Royal College of Surgeons of England. Charles Bell is, of course, the famous surgeon who discovered the function of the roots of the spinal nerves, and went from the Middlesex Hospital to occupy the chair of surgery at Edinburgh. "Bell's Paralysis" commemorates his name, while the "Anatomy of Expression," which is often quoted, reminds us of his artistic capacity. The contributions from Sir Thomas Watson, scholar and physician, were not numerous, but their existence should be recorded because his lectures in an expanded form became the most popular text-book on medicine between 1840 and 1876, when Bristowe's Treatise was issued, and to this day their teaching is often of the highest clinical value, while the writing will remain a model for all. Sir Robert Christison, professor of materia medica and forensic medicine in the University of Edinburgh, was the most expert toxicologist of his day, and did much to place his science on a firm foundation.

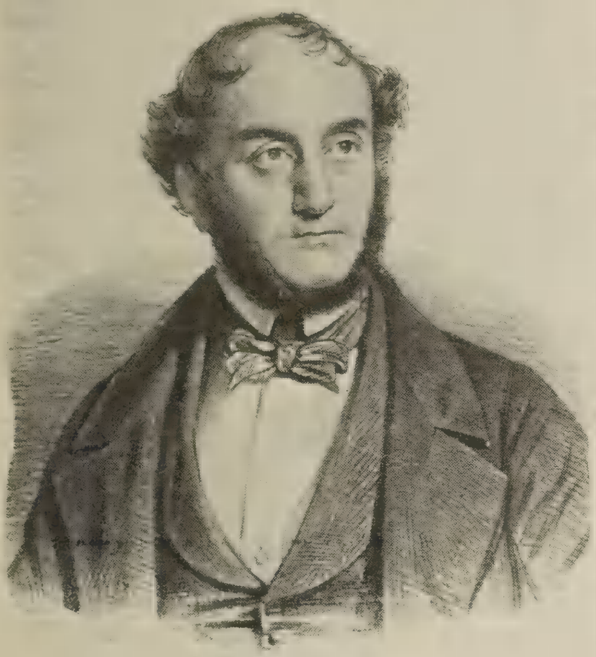

FIG. 15.—JOHN ELLIOTSON.

ENTENTE WITH FRANCE.

A good many of the cases recorded came from French hospitals, a close connexion between THE LANCET and the French medical schools having been instituted about 1830. For many years from the great charitable institutions of Paris there came to the pages of THE LANCET, supplied by the medical officers or translated by English students, short records of interesting cases, until about 60 years ago the first Paris correspondent of the paper was appointed, who was also the first regular foreign correspondent of the journal. In this way THE LANCET got into touch with Orfila, the founder of modern toxicology, who after ten years of work as professor of medical jurisprudence had been nominated Dean of the Faculty of Medicine at Paris. In the pages of THE LANCET there appeared translations of Orfila's work on the detection of poisons, the articles being accompanied by interesting notes of cases where Orfila's evidence had directed juries towards the finding of correct verdicts. Further, several members of the original staff of THE LANCET had done their clinical work in Paris, and when the courses of study at the London hospitals, or the anomalies of English medical education were the subject of discussion, the invariable habit of THE LANCET was to draw comparisons between what happened at the Paris hospitals or at the University of Paris and what prevailed in England. In this way a very close bond was set up between THE LANCET and French practitioners; French medical literature was reviewed in what we should to-day consider a cursory manner, but was none the less creditable to a weekly paper. As a result of this *entente* we find translations of excellent lectures on medical pathology delivered at the University of Paris by

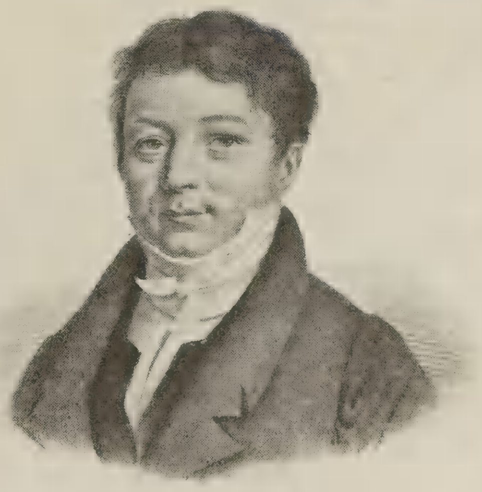

FIG. 16.—FRANÇOIS MAGENDIE.

G. Andral, many of Dupuytren's clinical lectures, and still more notably a long series of lectures by François Magendie (Fig. 16), the great French physiologist. The fame of Magendie may have been overlaid by that of Claude Bernard, but there is no doubt whatever that he was in his day one of the greatest physiologists. His lectures were translated into every language, he made discoveries in anatomy, and was an innovator in laboratory procedure, and the issue of his teaching in English form was both a progressive and useful movement. Dupuytren was the head surgeon at the Hôtel Dieu, a remarkable operator, who went round his wards daily with a crowd of cosmopolitan students at his heels. He was devoted to his profession, and left a considerable portion of the large fortune which he amassed to benefit a chair of anatomy at the École de Médecine.

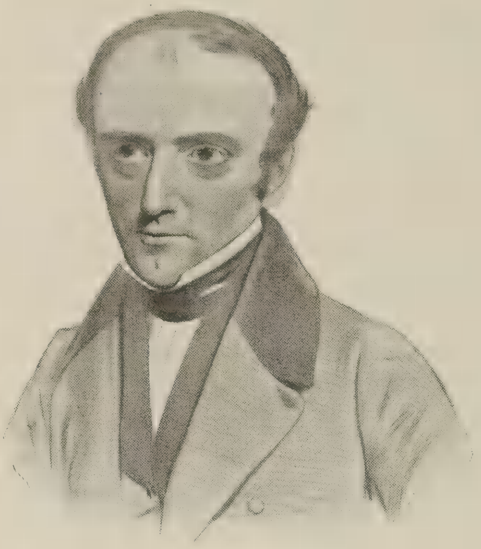

FIG. 17.—ROBERT GRANT.

Mention of Andral makes an allusion necessary to the stress laid upon the subject of phrenology in the early years of THE LANCET. Both at this period and for some years to come this was perfectly natural, although later attempts have failed to correlate the doctrines of phrenology with the observations of modern pathology, and especially with localisation of cerebral function. The action of THE LANCET in booming Gall and Spurzheim was not a very successful piece of prophesy; none the less, those who love to trace among the developments in scientific medicine the activities of the alchemists will always hold the work of these observers and the principles of "cranioscopy" to have some logical connexion with the discoveries of Hughlings Jackson and Ferrier. Phrenology, at any rate during the first 40 years of the past century, had many highly scientific followers as well as some acute scientific critics, and Wakley's immediate supporters belonged to both schools. In Paris, Andral, whose lectures ran serially in THE LANCET for a year or two, and Broussais, whose work was more than occasionally referred to or translated, were immediate disciples of Gall, and favoured the progress of phrenology as a system of psychology without basing their faith upon the popular idea that the relative size of certain contours of the brain both dictated the shape of the external covering and the disposition for mental impulses. Elliotson was found on the romantic side in the controversy, but Bell and Brodie were strongly opposed to it, and considered it impossible to estimate brain development from skull shape.

Alongside these two famous Frenchmen were published in serial form Prof. Robert Grant's (Fig. 17) lectures on comparative anatomy and physiology, and Anthony Todd Thompson's (Fig. 18) lectures on therapeutics. Grant, who had been recently elected Professor of Comparative Anatomy at University College, and who had been elected F.R.S. as a comparatively young man, probably devoted too much time to teaching, so that although he was a companion of Darwin, and corresponded with all the great naturalists of France, Holland, and Germany, his original work hardly justified his popular name of the Cuvier of England, but his lectures in THE LANCET had a very favourable reception. Anthony Todd Thompson was also a professor at University College, his subject being materia medica and therapeutics. His career was a fine example of the development of the general practitioner, for in that capacity he joined the staff of the *London Medical Repository* under Copland. The series of lectures on materia medica and therapeutics in THE LANCET were practically a new shape given to previous work on the subject, and in a still later form became the substratum of the British Pharmacopœia. Thompson was a man of wide learning and practical outlook, and the publication of his lectures advanced the prestige of the paper.

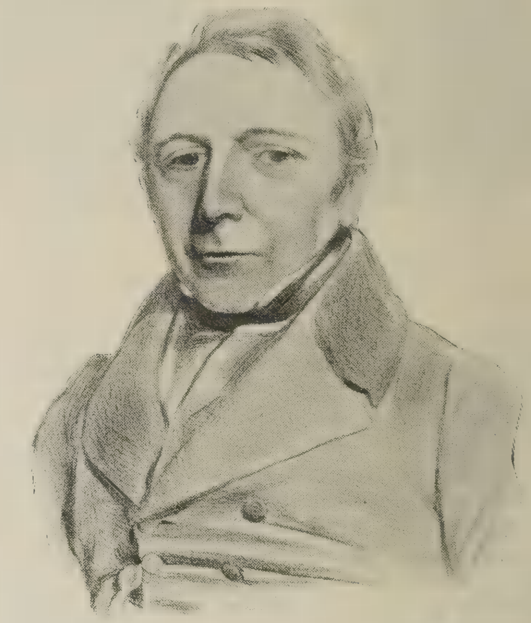

FIG. 18.—ANTHONY TODD THOMPSON.

Other notable clinical lectures which appeared during the period were by Benjamin Brodie (Fig. 19), Charles Bell, J. G. Guthrie, Thomas Wardrop, Benjamin Travers, and Robert Liston (Fig. 20). Their lectures were good examples of the teaching of the day, and their publication show that although the pages of THE LANCET were as critical as ever about hospital administration and the constitution of the corporations, the leaders of those corporations and the principal members of the staffs of those hospitals decided to allow their work to appear in the columns of THE LANCET. It may be thought that they did not so much allow their lectures to appear as that the law courts had made it difficult for them to take up the position that the lectures were their private property; but, as a matter of fact, they were, for the most part, real coöperators in the publication. First, they corrected the abstracts and résumés so as to perfect the words of their own teaching, but secondly, they found two things—that their material position as practitioners gained from the publicity, and that the comparatively novel habit of printing their lectures provided them with excellent material for more extended literary work. This was so in the case of Sir Thomas Watson, and in later cases, for example, in that of Erichsen, the skeleton of whose world-famous text-book appeared as a serial in THE LANCET.

FIG. 19.—SIR BENJAMIN BRODIE.

THE CHOLERA EPIDEMIC OF 1831.

The subject of the greatest interest to the public and medical profession alike during all the period we are now discussing was cholera, which, having made its appearance in Europe by way of Persia and Russia some five or six years previously, spread through the north of Europe, and appeared in the northern parts of England in 1831. For some 15 months the disease prevailed in many of the large cities of Great Britain and Ireland, and the pages of THE LANCET are full of clinical accounts from which much can be learned even at this time as to the onset of the disease. The pathological considerations would not now be taken very seriously, but the attempt to find remedies must command respect. Every conceivable method of combating the disease by internal remedies, vegetable and mineral, by stimulation, by bleeding and depletion, by baths, by friction—all had their advocates. One fact is outstanding, and is so taken for granted that it is hardly ever alluded to—namely, that at a time of natural and deep apprehension the medical profession had done and would do its duty everywhere and anyhow in the face of the raging epidemic. The intimate connexion at the time of THE LANCET with French medical thought was well illustrated by a furious article against the dissemination by Louis Phillipe's Government of official cholera medals, 1000 in number, commemorating personal bravery during the epidemic in France. While the medical profession stood foremost among the proper candidates for such medals, the King's advisers placed upon the official list no hospital *internes*, few officers of public health or of the hospitals, few of those who had really assisted the medical profession, a number of bureaucratic and political personages, sisters of charity, and quacks, among whom is singled out by THE LANCET for special notice a M. Beliol, whose advertisements "to cure the itch, the tetters, and secret diseases are pasted on every wall in Paris." Prof. Magendie, to whom one of these medals was awarded, returned the decoration to the Ministry.

FIG. 20.—ROBERT LISTON.

POPULAR JOURNALISM.

ILLUSTRATED BIOGRAPHIES.

IT is interesting to note that two methods which have over and over again been adopted by lay papers for the popularisation of their contents were hit upon by THE LANCET in the early thirties—namely, the publication of biographies of living persons of distinction or official position, and of open letters to similar persons.

The first series of "medical portraits," as the biographies were called, started in THE LANCET in 1833, and was a ruthless piece of writing. The subject selected was Sir William Blizard, "the testy knight of collegiate scowl and hospital vulgarity." Sir William was terribly old—older than the lithograph here reproduced (Fig. 21) would suggest, and a glance at his portrait on p. 696 will show that he had been a handsome man. It might have been thought that his age entitled him to compassion, but it must be remembered that it was exactly his age, coupled with his positions at the Royal College of Surgeons of England and the London Hospital, which constituted his chief offences. It was part of the general compaign of the paper against the constitution of the College and against the scheme for the education of the medical student that the power had got into the hands of old people, who proceeded to instruct and examine the students without any familiarity with existing facts. Sir William Blizard must have been nearly 90 years of age when his portrait and biography appeared in THE LANCET, and appended to it were notes of his teaching in the wards, which were intended to expose his senility, and which succeeded in so doing. Here is one of the notes :—"Sir William (*turning to a case of diseased testis*): 'When I took this case in I thought it was scirrhus epididymis. What are the diagnostic marks of scirrhus? Well, I will tell you. Its peculiar hardness and a sense of specific gravity. I have blistered this, and I dare say when the blister has healed the man will be quite well.'" The suggestion of THE LANCET was that such teaching was worse than worthless, for it conveyed no accurate information and made the recipient feel that he was the intellectual superior of his instructor. The writer described such teaching as "a sorry spectacle," and devotes a column and a half to indicating that by birth and education nothing better could have been anticipated, and that if at any period in the unfortunate knight's career he had given evidence of higher things he was now too old for more to be expected.

Among the other biographies which follow, and which are all of them very frank and many of them uncomplimentary, there is an excellent one of Sir Charles Bell illustrated by a sketch drawn in the theatre of the College of Surgeons while Bell was lecturing, and there is also a dramatic portrait accompanying some notes on the career of that singular Frenchman, M. Clot. Clot was a Marseillais, and took his degree at Montpellier. He went to Cairo on the invitation of the Pasha of Egypt in 1831. Under the Pasha he organised a system of medical education on European principles at Abouzabel, near Cairo. Here he lectured on anatomy, physiology, and surgery, and added to the buildings a maternity clinic in which "the art of accouchement is taught to negresses and Abyssinian women." Partly because M. Clot was really a competent surgeon and a remarkable man, and partly because the Viceroy or Pasha of Egypt held him in high admiration, he obtained a large practice in Cairo and a more or less European reputation. The accompanying portrait is described in THE LANCET in the modest language of the day as one "possessing great fidelity, the features of the expression of the Bey being delineated with much facility." (Fig. 22.)

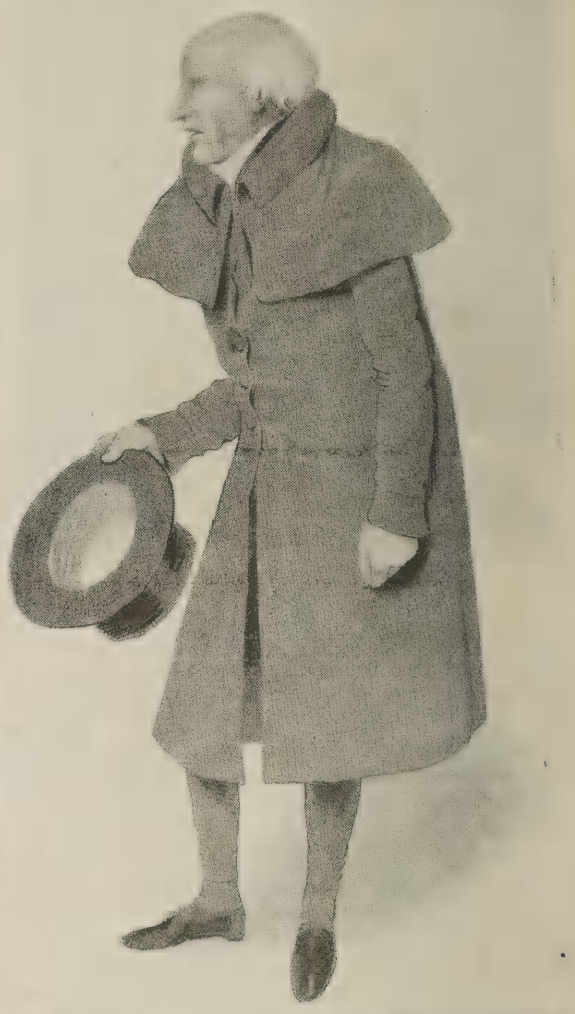

FIG. 21.—SEMI-CARICATURE OF SIR WILLIAM BLIZARD

Other persons to be commemorated were William Lynn and John Elliotson, but the first series of medical portraits was not a long one, and gradually they were discontinued to be reintroduced in a different vein some 15 years later. The biography of Elliotson is appreciative, but that of Lynn is an indictment of the famous lithotomist as a vain and garrulous old man, even while doing justice to his work as anatomist and surgeon.

“INTERCEPTED LETTERS.”

A series of amusing and scurrulous communications, entitled “Intercepted Letters,” enlivened the pages of THE LANCET for some years, beginning almost simultaneously with the illustrated biographies. The idea of writing them has been attributed to Wardrop, and there is some internal evidence that he actually wrote several of them, but Wardrop would only have been following precedent. The opportunity for topical criticism and indiscreet comment offered by such contributions had made them a popular weapon in the hands of provocative journalists, while the code of manners in the reign of William IV. was not that under which we live to-day. The great master along this line, “Junius,” it will be remembered, addressed his victim directly, whereby only one person was attacking and, for the most part, only one person was attacked. The “Intercepted Letters,” as they appeared in THE LANCET, gave greater opportunities, though the concentration was lost, because the correspondence was usually as damaging to the person from whom the letter purported to come as to the person who was described as having received it.

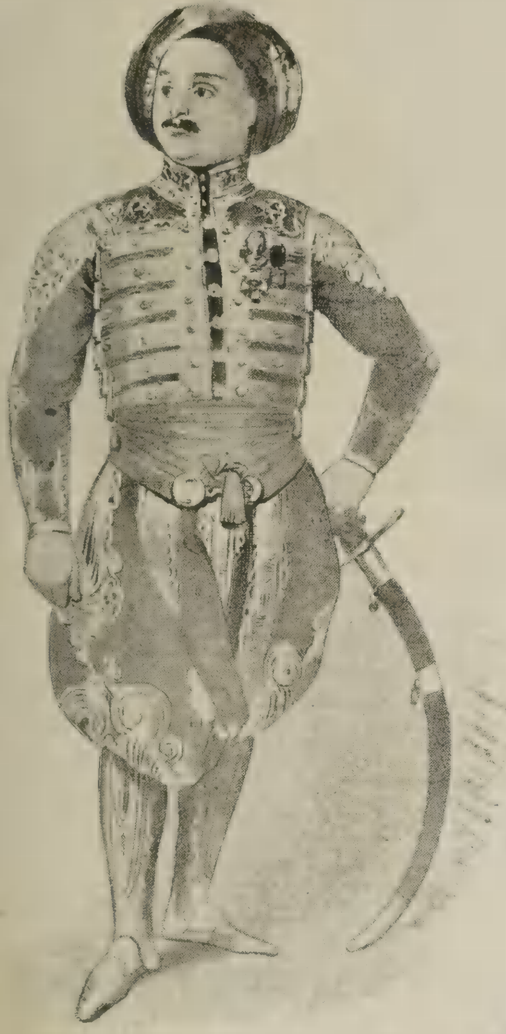

FIG. 22.—SEMI-CARICATURE OF CLOT BEY.

Two examples may be given of these Intercepted Letters. The first is addressed to Sir Benjamin Brodie, at that time becoming a prominent member of the Council of the Royal College of Surgeons of England. It is very long and commences as follows:—

> “It is of first-rate importance that you ride the President of the College with a sharp bit.”

The letter continues:—

> “Pray tell me with your wonted candour if Macleod has applied to you for any more subscriptions. I am so disappointed at the want of anything like talent in his journal that, for myself, I will pay no more. After all, what a world this is. Its events may be a comedy to some, but to most of us, my dear friend, they are a tragedy. I took much pains to aid the *Gazette* at starting, and I distributed hundreds of the prospectuses amongst all sorts of persons, particularly the bishops and top apothecaries. Nay, you may remember that so far did I go as to have one placed in each plate at the first dinner I gave after its publication was announced, and told the surgeons and physicians who did me the honour of eating with me on that occasion, that at last they had a journal which they *could* read, and I hoped they would warmly support it. Yet what good has all this done? Why a reform in the profession seems close at hand, in the teeth of Macleod and his assistants. By the by, I hear that Macleod denies to some people that he any longer edits the journal. Tell him, if he persists in that statement, not to be seen entering the assistant fabricator's house so frequently, since for the sake of secrecy he has removed his papers to that quarter.
>
> I further hear a report that Mr. Travers has shown a disposition to cut us. Gracious Heavens. Who next? Let someone go to Bruton-street and ascertain what is the fact. It can hardly be true. Where the inducement? He would gain no credit on the other side. The revolutionists would not have him at a gift I suspect. So the dear Prince at Kew is going to Berlin. What a sad compliment to the eye-doctors of London. We managed well, I think, to keep Wardrop from being called in, though it would almost have been better to allow that than lose the family altogether for so long a time. Graefe paid the English druggist the compliment of taking much medicine with him for the Prince. A friend of mine told me that he saw a mahogany chest full in the Baron's house at St. James's. I have time to say only how devotedly I am
>
> Yours,
>
> * * * * * * * * * * * *
>
> Leicestershire, Sept. . . . , 1843.
>
> PS.—Can it be *our* Lockley that was examined at the low inquest which I saw reported in the papers to-day? Surely he does not accustom himself to attend such vulgar proceedings when he has seen the case before death. The hospital surgeons never go, though the deceased may have died under their hands. They always send the ward sisters, or the dressers. Has Lockley no apprentice?”

This letter, of course, teems with insults, from its first suggestion that the President of the College of Surgeons was supine, to its last that Fellows of the College of Physicians could have nothing to do with inquests. The letter is signed with five asterisks followed by seven asterisks, the suggestion being that it is written by Sir Henry Halford, President of the Royal College of Physicians, whose position at Court was made the subject of constant and cruel reference. The *Gazette* in question, is Dr. Roderick Macleod's *Medical Gazette*, which at that time was very critical of THE LANCET, as indeed it might well be, seeing that the following open message had just been sent to Macleod in an editorial article. “Enough of this; there are brutes that are not worth the lash of ½*d.* whipcord.” Dr. Macleod was assisted by Halford and others in bringing out his paper with a mission to counteract the disrespectful poison disseminated by Wakley.

The second "Intercepted Letter" is quoted as showing the extraordinary liberty, not to say licence, which characterised the columns of a scientific journal of the day. Here it is made perfectly clear whose letter is supposed to have been intercepted, for it is dated from ——— Hall, Leicestershire, is signed H. H., and the page on which it appears is headed "Sir Henry's Medical Affairs." Sir Henry Halford, whose original name was Vaughan, had taken the name of Halford on succeeding to a Leicestershire property, and the libel is unpardonable :—

> "Dear Dr. Turner,—None but a man endowed with a sentimental mind like your own can enter warmly and feelingly into my present position ; and I do assure you, my dear friend, that the quietude and repose of the country, after all I have gone through—all the mortifications and annoyances I have suffered during the last London season—is quite a balm to my troubled mind. I am indeed glad to get something to occupy me apart from my wonted habits and avocations, and though it may appear ridiculous to you, I do assure you it is true that the little annoyances which are inseparable from the life of a *country squire* do me good. When I am brooding over the downfall of professional legitimacy or the questions of the Parliamentary Committee, I am absolutely not sorry, even if my bailiff comes to tell me that my sheep have sold for less money than they cost six months ago ; or my gamekeeper to say that a hoard of poachers have murdered all the game ; or my groom to announce that my favourite riding horse has broken both his knees. I would say on the principle that guides us on the treatment of diseases—the principle of *revulsion* of *diversion*—that all these things do me good ; and a good practice it is too to put a blister on a ladie's coccygeal region, when she complains much of her head.
>
> I hope you are keeping a sharp look-out after my patients during my absence ; and when I take my next run up to town, the more of them you can get to meet me in Curzon-street the better, as I will remain only one day. Never fail to tell everyone of them that in all my letters I particularly mention *their* names and make many inquiries about the progress of their particular case, and how the last prescription agrees with their constitutions. As I always take care that they consider my knowledge of their constitution minute and comprehensive, it is of importance that you strengthen that notion ; for during an experience of nearly 40 years I have ever found that nothing makes patients less likely to employ another medical attendant than the notion of the ordinary one—knowing their *constitution*. You can easily let anyone suppose that I am obliged to go to Windsor occasionally, as that will appear a good excuse for my being a day in London. The last accounts I received from the Castle were not very cheering. There is, indeed, nothing to be done there in the way of business. The King is wonderfully well ; and in place of stuffing and cramming his stomach with all kinds of trash, and then taking physic and getting me to unload the machine, like his late brother, my kind and ever to be lamented friend George IV., he lives most regularly, moderately, and soberly, and has *no complaints*. It is unfortunate for us, at this moment particularly, that he has a low opinion and such a dislike of physicians. He has abided by a determination which the Duke of ——— told me that he heard him express when he came to the throne, that he 'would be d——d if he would make an apothecary's shop of his guts, as his brother did.' He has a quite sensible surgeon living in the palace, so that if the least things go wrong, if any screw be a little loose, there he is in readiness. That is not right by any means. As to our gracious Queen, my Windsor correspondent writes me word that she has become a convert to the homœopathic system and is now under the guidance of a German doctor who is giving her (I suppose because she is a Queen) only the ten-thousandth part of a grain of some of his nostrums. Her little homœopathic medicine chest with all its little bottles is a nice little toy to amuse her. Lord Howe watches the effects of these wonderful millionth fraction pills, and I have never been nor am I likely ever to be consulted by her.
>
> I have got the periodicals regularly. I need not conceal from you, my worthy friend, that I am grieved and vexed to see extracts of my examination before the Committee printed in The Lancet ; and had I not been taken partly by surprise, and lost my temper somewhat during the examination, I should not have said so much, and attempted to show that the cause of our not making Fellows of the Licentiates was the defective moral character of the Licentiates. I confess it was a sad blunder on my part, to say in public that while we encouraged the Licentiate to practise midwifery, we considered it beneath the dignity of a Fellow to touch such things.
>
> Write to me anything that you hear is going on in Pall Mall, Blackfriars, or Lincoln's Inn Fields. I intend writing to Sir Astley about some vexatious things which I have heard respecting the certificate system. It cannot go on. How do little Benjamin's honours sit upon him ? I long to see *her ladyship*. Is it true that he has got a carriage in imitation of mine ?
>
> Write me everything ; and put your letters under cover to my son, which will save the postage.
>
> Yours faithfully,
>
> H. H."

"Little Benjamin" is Sir Benjamin Brodie, whose small stature is made a subject of frequent reference, for he is generally alluded to as the "little eminent."

Illustrated Biographies : A Second Series.

The second series of biographical sketches commenced with a life of Marshall Hall, to whom The Lancet in its early days owed much. All the great observer's extensive work in chemistry, physiology, hæmatology, and neurology was published in The Lancet as it appeared from the time when he took up his residence in London in 1826. A synopsis of the spinal system in a series of lectures by Marshall Hall provides another good example of famous work which first saw the light in the columns of The Lancet at this epoch. (Fig. 23).

Hall was at this time no longer a young man, for he had graduated in medicine some 40 years earlier, and had made his name both as physiologist and physician in quite other fields before he did his illuminating work on the nervous system. His researches were not appreciated at first at their true value. At the time of his death in 1857 he was engaged in preparing for publication in The Lancet a précis of his life-work, but in essentials that story is written in the columns of the paper to which he was so constant a contributor. In the biography opportunity is taken for an indictment of the Royal Society for the prolonged neglect of Hall's claims, when one cannot but feel that Hall might have been embarrassed by the methods employed. Failing any public or official recognition of Hall's work, the following suggestion was made which is worth quoting in view of the institution of the Order of Merit by the late King Edward VII.

> While the leaders of our armies and navies, our statesmen, our lawyers, our divines, receive the highest honours of the State, the cultivators of science, and especially of medical science, requiring the very highest order of mind, are comparatively neglected, and often forgotten. These things require reform. There ought to be an Order of Merit instituted, to which only the really meritorious should be able to attain. It might be in one class or in different classes, according to professions, &c. This Order of Merit should rank higher than any mere hereditary honour ; the possessor should be entitled to wear a distinctive decoration.

It is interesting that while the scope of the modern and most distinguished Order should have been prophesied in the words "only the really meritorious," the title of the Order should have been exactly indicated 70 years ago.

The next biography is that of Henry Clutterbuck, a contemporary of Lettsom, and therefore nearly 80 years old at the time the memoir was published.

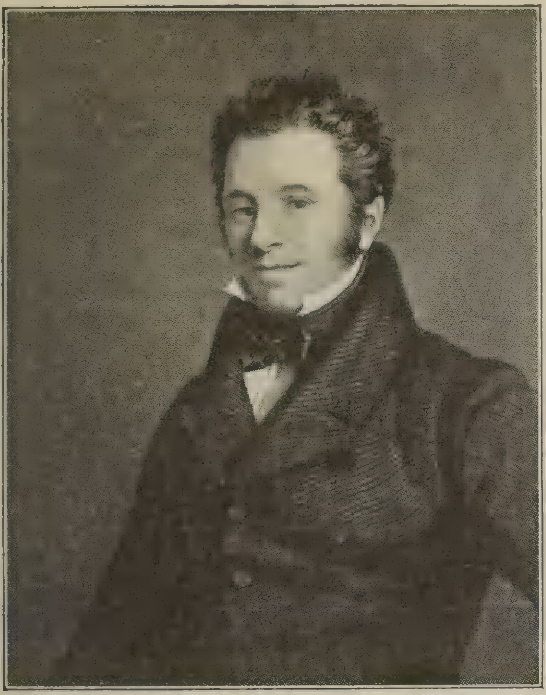

FIG. 23.—MARSHALL HALL.

He was in the forefront of the proceedings of the Medical Society of London, of which he was three times president, but it was his action, none the less, which led to the schism in the Society, resulting in the founding of the Royal Medical and Chirurgical Society, itself the parent of the Royal Society of Medicine.

Another biographical sketch was that of Bransby Blake Cooper, now senior surgeon to Guy's Hospital, in which ample justice is done to Cooper as a surgeon, and particularly as an anatomist. The lurid circumstances which led to a libel action against THE LANCET are only alluded to in these words: "The absence of animosity on the one part, and the kindly feeling on the other, preclude the necessity of dwelling on a subject which must be equally painful to both parties."

An interesting biography is that of Sir James M'Grigor, Director-General of the Medical Department of the Army, in which the ideal of the Army surgeon is placed very high when it is said "his duty is not to treat individual cases of disease, but to deal with the causes and prevention of large classes of disease." A letter from the Duke of Wellington is included, in which the Duke, not a "gusher," states of Sir James M'Grigor "I consider him one of the most industrious, able, and successful public servants I have ever met with."

Short biographies of Sir William Burnett, Director-General of the Naval Medical Service, and Prof. R. E. Grant, professor of comparative anatomy and zoology at University College, London, are among those that follow, and all the character sketches lay stress on the eminence of their subjects. Some correspondence accordingly took place, questioning the discretion of the Editor in publishing eulogies of living men. For the eulogies did not make the rollicking reading which was furnished by the old libels. For the most part the people were too well established in their position to gain any unfair professional advancement by the public notice given to them, but the series, which was intended to include 100 names, was soon dropped. Benjamin Travers, James Sime, Robert Lee, and Sir William Fergusson were among the last, the series actually closing with an interesting biographical sketch of Sir Charles Hastings. (Fig. 24.) The portrait reproduced will be recognised as that which is so familiar to us on the cover of the *British Medical Journal.* Hastings was the founder of the Provincial Medical and Surgical Association, and received in his efforts regular assistance from THE LANCET. He was a practitioner at Worcester, and physician to the hospital, and he published, with the assistance of personal friends, the *Midland Medical and Surgical Reporter,* a quarterly periodical in which he expressed the intention of publishing notes of interesting cases from provincial hospitals, so as to extend, for the benefit of general practitioners, knowledge of disease treated in the institutions. From this movement arose the Provincial Medical and Surgical Association, which held anniversary meetings with such success that in 1840 it was decided to issue a weekly publication, the *Provincial Medical and Surgical Journal.* The Association later became the British Medical Association, and the journal took the name of the

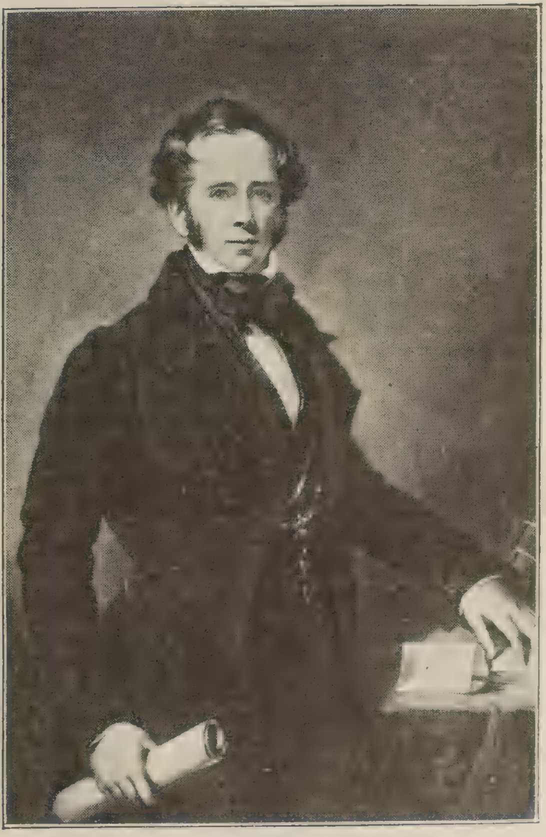

FIG. 24.—SIR CHARLES HASTINGS.

British Medical Journal in 1857. The work of the *British Medical Journal* has been for so many years and in so many places running parallel with the work of The Lancet, and the objects of both journals in separate ways have so often been identical, that no notes on the career of The Lancet would be complete without mention of the great journal whose life has been lived side by side with us. The intention of Hastings to distribute to general practitioners information from metropolitan centres was exactly identical with one of the reasons for the foundation of The Lancet, and all the efforts of the Provincial Medical and Surgical Association were warmly greeted in The Lancet. For some years the Association was satisfied with the issue of an annual volume, but in 1840 the *Provincial Medical Journal* was started, and with certain modifications in title ran for 16 years, when, by unanimous vote at the annual general meeting of the Provincial Medical and Surgical Association, the title of that body was altered to the British Medical Association, and its official journal became in the following year the *British Medical Journal*. That is a pedigree of antiquity for any journal, but if direct descent of the *British Medical Journal* be allowed from a quarterly periodical, the *Medical and Surgical Reporter*, the date of origin can be thrown back four years, while certainly the *Medical and Surgical Reporter* was edited by Sir Charles Hastings. In 1866 Ernest Hart left The Lancet and was appointed editor of the *British Medical Journal*, thereby leading to a break in relations hitherto friendly, but the ill-feeling was so entirely personal that when the leaders left off quarrelling peace was restored. As time went on, our great contemporary grew with the growth of the body whose views it represents, and while the increasing energies of the British Medical Association necessitated the publication in its organ of notices, agenda, and reports in connexion with its committees and branches, these committees and branches became the natural medium for putting into effect many of the movements which had been and were being advocated by The Lancet. In a short time the ill-feeling engendered by Hart's transference of his services from one paper to the other died down, and those who are at present in control of The Lancet, though not conspicuously young, are not old enough to remember when anything but good feeling prevailed between those responsible for the conduct of the two journals.

THE LANCET IN THE 'FIFTIES.

The death of Thomas Wakley occurred in 1862, until when he remained his own editor-in-chief nominally, but as a matter of fact he had taken but a supervising part for some years, his youngest son, Dr. James Wakley, having come straight from graduation to assist his father in 1852. There was consequently no change in the general policy of the paper, and no overt change in editorship. It was left for the son on the one hand to continue the work which had been begun by his father, and on the other to develop that work and also to initiate new activities as a progressive profession demanded their exercise.

When the first Thomas Wakley died it was publicly claimed for him not only in the columns of his own paper, but also in many other places, that he had started principles of reform and in large part secured their realisation. Thus, and above all, had been advanced the status of the medical practitioner, while there were conferred upon medical science, and therefore on the public, the conspicuous advantage of proper opportunities of development in divers directions. Wakley fought the battle of the medical student and the general practitioner at a time when universities and corporations seemed to regard both as persons who should pay fees but whose interests were otherwise of no consideration. He exposed impostors and denounced quackery, while he published medical information which would otherwise have been entirely lost, doing so in the first instance at considerable pecuniary risk, if not in defiance of the law at the time.

So much we hope has been shown.

A Critical Period.

A critical period in the history of The Lancet was reached by the year 1850. The paper had now been established for more than a quarter of a century and enjoyed a reputation for soundness, frankness, and large endeavour, which had spread over the country and upon the continent. Stress, it must be confessed, should be laid on the word endeavour, for leading editorial pronouncements, backed though they were now with the names of eminent persons, were apt to foretell immediate reforms in large directions where either the reforms did not follow or followed to a degree incommensurate with the promises made. At the same time the paper had become assured in its high standing; and while the signing contributors to its columns included many leaders of the medical profession, the editorial staff was known to be recruited from among them or their inevitable successors.

A few prominent contributions are again mentioned to show the endeavour of the paper to keep its public scientifically informed. Lectures by Sir John Simon (Fig. 25) on general pathology provided readers with what was badly needed at the time—namely, a definition of pathology, a scrutiny of its scope and interdependence upon other ranges of knowledge, and a summary of its achievements at the time. Simon is so well known as the father of sanitary science that we are apt to forget that his magnificent labours in the cause of public health were prefaced by pathological work which had been rewarded by the Fellowship of the Royal Society when he was quite a young man. The portrait shows him at the end of an extremely long life. His penetrating survey of pathology, written when he was already a medical officer of health, brought him in 1850 in close touch with the group of men who founded the Epidemiological Society. The objects of that Society were "to study the causes which lead to premature death and preventable disease and to advise administrative bodies

thereupon," and how Simon, as administrator, carried out this programme upon his appointment as first medical officer of health to the Corporation of the City of London, and later as first medical officer to the Privy Council, is a matter of notoriety.

Another valuable set of clinical lectures, running simultaneously, consisted of a series of surgical cases recorded by John Erichsen. This formed a scenario for the great work on surgery, which was the most popular text-book on that science for more than 30 years after its first appearance in 1853, when it superseded Samuel Cooper's "bible of surgery." Erichsen's "Science and Art of Surgery" was avowedly written to form a text-book in fuller explanation and exposition of his clinical lectures, and this is the reason why, in its first shape, certain sections of surgery were not included. They were sections on which he himself had not delivered clinical lectures. The last edition of this work was published as recently as 1895, edited, in a form now much altered by necessary additions and revisions, by the late Marcus Beck and Mr. Raymond Johnson.

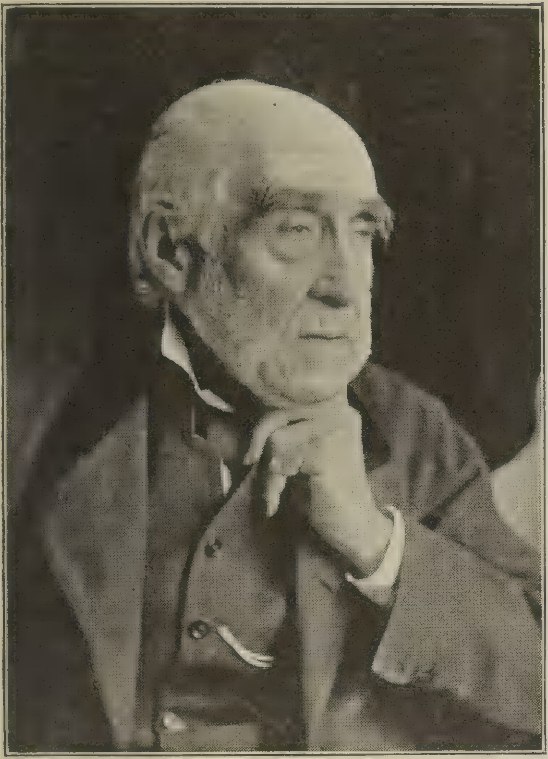

FIG. 25.—SIR JOHN SIMON.

ORGANISED MOVEMENT AGAINST TUBERCULOSIS.

Two movements should be noted as receiving particular prominence in THE LANCET between 1850 and 1860 because of their permanent bearing on medicine, and because the views on the subjects which can be found scattered throughout the pages of the journal show that certain of the difficulties which are still with us were realised in those early days. In 1850 there appeared the first medical report of the Hospital for Consumption and Diseases of the Chest at Brompton. It is a brief abstract of a brief document, but it shows how modern our grandfathers and even our great-grandfathers were in their grasp of the circumstances. The cause was hidden from them, as it was from us for 30 further years, but on the contributory influences to the spread of tuberculosis they were wonderfully clear and well informed. Simon's annual reports, which cover the years between 1848 and 1855, are admitted to be a landmark in the history of sanitation, and these systematic surveys of the general sanitary circumstances of the City of London ventilated questions of housing and other social conditions of the labouring classes whose relation to tuberculosis was immediately seen by the group of medical men who first faced the special problems of the disease.

The statements in the first report of the Brompton Hospital for Consumption were deduced from an analysis of 4000 cases arranged under three heads, the first containing observations on the influence of sex, age, social condition, occupation, and hereditary predisposition, the second dealing with symptomatology, and the third with the results of treatment. The conclusions on the influence of sex immediately contradicted the wide impression that females showed a greater liability to phthisis than males ; the influence upon the figures of occupation and social conditions—trades, occupations, and so forth—were reinforced with excellent tables, checked by the records of a general hospital for the sake of comparison ; and the incidence of phthisis was noted upon those who were compelled by occupation to work in close, ill-ventilated, and over-heated rooms, to sit for many hours each day in a posture unfavourable to the free action of the muscles of respiration, to breathe an impure atmosphere, and to forgo exercise in the open air. We may be certain that the memory of Hood's "Song of the Shirt," which had appeared in *Punch* some ten years earlier, decided the particular reference in THE LANCET to the plight of seamstresses, with regard to whom it is stated that they formed one-fifth of the total number of female patients at the Brompton Hospital. The results of treatment at this date could do little more than indicate that the disease was arrested in about 12 per cent. of the males and 7 per cent. of the females, the value of the figures being, as we now know, nil, for nothing was said as to the stage of the disease on admission, the evidence relied upon to prove arrest, or the duration of that arrest. The absence of any successful course of remedial treatment was remarked upon by one Dr. Francis Ramage in uncomplimentary terms because the hospital did not adopt an inhalation apparatus as devised by himself. The appearance of a long letter by him in the columns of THE LANCET was a little remarkable as, some 20 years before, when the famous quack, John St. John Long, was placed in the dock at the Old Bailey charged with manslaughter, Ramage defended Long's methods. The exertions of THE LANCET had brought this surprising adventurer, whose pass-book testified to the imposing income of £13,000 a year, into an awkward position and secured a verdict of manslaughter against him. And when Ramage, an M.D. of the University of Oxford and a Fellow of the Royal College of Physicians of London, commended Long's treatment in the columns of the *Sunday Times*, THE LANCET said that Ramage had placed himself outside the pale of the profession, and the Medical Society of London expelled him from their body. Dr. Ramage brought an action for libel, obtained a farthing damages, and remained critical of the methods of this paper henceforth.

THE TREATMENT OF INSANITY.

The second movement to which constant allusion is made throughout this period was one directed towards the more intelligent treatment of mental disease. The subject gained prominence by the starting of a testimonial to John Conolly (Fig. 26), the asylum reformer, whose work at Hanwell had been favourably noticed when many quite humane persons considered it too revolutionary. Conolly's was an interesting career. He began as a soldier, became a medical student in France, and graduated in Edinburgh, presenting a thesis upon insanity. For a period, however, he seems to have lost his interest in psychological medicine, practising in the provinces, and taking up municipal work. But shortly after the foundation of THE LANCET we find him in London as professor of the practice of medicine in University College, the nucleus of the University of London, and during his term of office he published a work entitled "Indications of Insanity." Later he left London to hold the post of inspecting physician to certain provincial asylums, and he was subsequently appointed resident physician to the Middlesex Asylum at Hanwell, then the largest institution of the kind in England. His lectures in THE LANCET detailed the modern methods of therapeutics, and were republished in a volume which was widely read. A rational system of treating the insane, instituted in France, had been in practice for some years under William and Samuel Tuke at York, and Charlesworth and Hill at Lincoln. Conolly, when he took charge of the Hanwell Asylum, removed every form of mechanical restraint, and during the 12 years during which he was the head at Hanwell a revolution was effected in the treatment of the insane throughout the country. He created in this short time a fervour for reform amongst the public, which took effect later in THE LANCET, when, as a sequel to the Analytical and Sanitary Commission, an inquiry into the conduct of lunatic asylums was set on foot.

THE CONDUCT OF LUNATIC ASYLUMS.

A further inquiry was made by THE LANCET into the conduct of lunatic asylums in 1875, which it will be convenient to tell of now.

The purpose of this inquiry was to ascertain the general character and adequacy of the material provision made for the insane in asylums and the conditions of their daily life, but it was also hoped to collect and collate statistics of cases where the history went back as far as ten years so as to estimate the results of treatment. Lastly it was definitely set down as an object of the inquiry "to discover measures and as far as may be possible to formulate a system of treatment adapted for the cure of remediable or recent cases and the relief of chronic or incurable cases." The inspection of lunatic asylums promised under such a scheme met not only with approval but with promises of coöperation from certain medical superintendents and officers of asylums, and it is probable that Henry Maudsley was the actual originator of the plan to be followed. But the inquiry came to little, James Wakley having for once failed to find the right lieutenant.

FIG. 26.—JOHN CONOLLY.

The investigations were entrusted to a curious and able man named Mortimer Granville, and the choice was not a happy one. Granville, who had not for many years been in actual medical practice, was an industrious and facile writer and had attained a considerable position as a political journalist, editing for a time one of the big London evening papers. He proposed himself to Wakley as able and willing to write the articles and to have them supervised, but he did not disclose the fact that for his political services he had been promised a Home Office appointment, and that his selection to make an independent inquiry for THE LANCET would probably speed his selection. But Maudsley became aware of the fact and withdrew his support of THE LANCET inquiries, evidently believing that the paper was privy to an intrigue for the personal advancement of one of its contributors. The case was cleared up, but THE LANCET inquiry into the conduct of lunatic asylums was a failure. Granville ceased to be on the staff of THE LANCET, but had for a considerable period great success with the public as a consultant physician.

The reports on the County of Surrey Asylum at Brookwood and the Middlesex County Asylum at Hanwell are distinctly valuable documents. The criticism of the building at Hanwell as it was at that time must have been quite useful to all who were working for the improvement of the treatment of lunatics. The building is described as a vast and straggling one in which "the characteristics of a prison, a self-advertising charitable institution, and some ambitious piece of Poor-law architecture clamour for precedence. The gates are kept by an official who is attired in a garb as nearly as possible like that of a gaoler. All the male attendants are made to display the same forbidding uniform. Whether the justices of this county are especially proud of their livery it is not for us to determine, but in the name of common-sense and humanity we must warmly protest against the weakness of parading it perpetually before poor creatures whose only offence is their misfortune, and whose distressing malady should deter governing authorities from obtruding what is, beyond all question, a source of irritation. County asylums are now most unwisely treated as depositories for ex-criminal lunatics, and even prisoners who have become insane before the expiry of their terms of confinement. One of these morbid miscreants in a ward will make the uniform known to the ordinary inmates, and all idea of homeliness is immediately transformed to a depressing sense of imprisonment; while that large class of lunatics who are partly insane and partly vicious instantly take to prison practices, and readily become imbued with the pestilent doctrine of criminal lunacy, that being insane, they may do wrong with perfect impunity." The report acknowledged that the Committee of Visitors at Hanwell were doing much to improve the conditions of life for the lunatics, but gave the impression that the particular reform which was to have been advocated—namely, segregation of commencing cases—was badly needed.

THE ANALYTICAL SANITARY COMMISSION.

No activity in the columns of the paper ever caused so much public attention as the institution in 1851 of THE LANCET Analytical Sanitary Commission. We must retrace our steps in order to tell an unbroken tale.

Incontrovertible evidence had been gradually accumulating that the popular belief in the prevalence of food adulteration was based on fact, and advances in microscopy and analytical chemistry, which were referred to in scientific articles without any particular reference to foodstuffs, suggested that weapons had recently been furnished which would enable an effective attack to be made upon the adulteration, sophistication, and substitution which were undoubtedly taking place in many quarters. It was decided by THE LANCET to issue the results of microscopical and chemical analyses of the foodstuffs, solid and fluid, in general consumption. The labour implied in such an inquiry, if it was to be undertaken with proper thoroughness and security from error, and if its range was to be so large that the great public benefits anticipated would be secured, made cautious members of the staff reluctant to undertake so brave a departure, and, as a matter of fact, the institution of the campaign hung fire for a year or so. But during that year new facts were obtained and new evidence was collected in directions which had been foreseen in constant references made by the paper for 20 years to certain commercial practices.

On many occasions the first Wakley showed himself to have real journalistic *flair*, and this is a case in point. The fact of the Great Exhibition of 1851 being held in London decided him to start the movement for ensuring a pure food-supply at a time when the metropolis and its neighbourhood were certain to be densely crowded, when catering would be disorderly, and when a prevalence of high prices would lend pressing invitation to dishonesty. Accordingly, in the grandiloquent style of the period, he opened his agitation in favour of legislative reform with the statement that THE LANCET would now undertake—

> "a task large enough to engage the attention of the Government of this country. With the exception of officers to observe and report upon diseased meat or fish, the public authorities take no cognisance of the adulteration and poisoning by the slower, but equally sure mode of adulteration of food and drinks. We will bring the microscope and the test-tube to bear with unerring truth upon things hidden and secret enough to the unaided senses, for the protection of the public, the advantage of the fair trader, and the ultimate exposure and punishment of the fraudulent one."

This sentence formed a general introduction to the new inquiry. The preface to the series of articles issued under the generic title of "THE LANCET Analytical Sanitary Commission," further defined the scope of the proposed inquiry as an attack upon prevalent methods of adulteration so thorough and uncompromising that it would frighten individual evil-doers out of their ill-behaviour and open the eyes of Parliament to the necessity for State interference. "Boards of Health and Commissions of Sewers," said this preface, "have been appointed by Government, but there is no State protection of food":—

> "We propose, then, for the public benefit to institute an extensive and somewhat vigorous series of investigations into the present condition of the various articles of diet supplied to the inhabitants of this great metropolis and its vicinity, and probably the inquiries will be extended to some of our distant cities and towns. One special feature of these inquiries will be that they are all based upon actual observation and experiment; the microscope and test-tube throughout these investigations will be our constant companions. We shall borrow but little from the writings of others, preferring to labour and think for ourselves and to work out our own conclusions."

The wish of THE LANCET to be thorough was indicated by the stated intention of publishing the names and addresses of the parties from whom the different articles were purchased where examination had proved unsatisfactory, unless the fraudulent practices were stayed within the next three months. The name of the principal expert engaged on the inquiry was not at the time disclosed. It was Arthur Hill Hassall, but readers of THE LANCET and many members of the public were quite able to identify the authorship, inasmuch as Hassall had published in THE LANCET interesting illustrated articles revealing the use that could be made by an expert of the microscope and disclosing also his capacity as an analytical chemist. Associated with Hassall was Henry Letheby, then lecturer on chemistry at the London Hospital, and later, when the fruits of the inquiry were seen to reflect enormous credit on its originators, some dispute arose as to the exact parts played by different persons. The Commission was devised by the Editor of THE LANCET, the plan of its working was based on previous work done by Thomas and William Henry, well-known chemists, the bulk of the microscopical examinations in the first five years, amounting to over 2000, were made by Hassall, while Letheby conducted all the important chemical analyses. The first articles of food to be made the subject of microscopical and chemical examinations were coffee, sugar, arrowroot, London water, chicory, mustard, bread, cocoa, oatmeal, tea, milk, butter, and various spices, sauces, and preserves. The investigations were thorough; they left no loophole for offenders; they allowed no possible cavil on the ground of doubtful honesty of purpose, and they were simple. All precaution was taken to avoid error, and proved effective, for it would appear that the analyses were challenged once only.

The first foodstuff dealt with was coffee, and began with the statement that coffee was largely adulterated, when the dilemma in which those who denied the proposition would be placed was indicated by figures. Official returns showed that the population of the country had increased; temperance advocates provided statistics indicating a greater use of the commodity; while the Exchequer figures proved the amount of coffee imported, as exposed by the coffee duties, to have dropped between 1849 and 1851 by £50,000. The significant fact was mentioned that during this period chicory was being cultivated in large quantities, and yet little or none of it was retailed to the public as such.

Then followed careful and illustrated descriptions of the microscopic appearances of the unroasted coffee berry, the roasted berry, and its investing membrane. These appearances were contrasted with illustrations of roasted chicory root, while the minute structures of corn-flour, potato-flour, and bean-flour and ground coffee were shown for comparison. The results of such microscopical examination of 34 different coffees of all qualities and prices justified the predictions previously made in THE LANCET; 31 coffees were adulterated, the 3 exceptions being retailed at a high price. Chicory was present in 31 instances and other flours in varying quantity in different samples. In some instances the coffee present amounted to less than one-fifth of the bulk of the samples taken, and the rather astonishing calculation was added that, using the figures of 1849 as a basis of calculation, the revenue had been defrauded during that year of no less a sum than £300,000.

The results of a second or confirmatory examination were then appended. Here 20 samples of various coffees had been purchased at the establishments of different metropolitan grocers and tea and coffee merchants, and in every single case the coffee was found to be adulterated, in 16 the tampering being of the grossest character. To defend the honest trader from his fraudulent competitors the names and addresses of the dealers from whom the pure samples had been purchased were printed in full, and the names of the adulterators were promised at a later date unless subsequent examination of their wares showed them to have profited by the warning.

At the expiration of the three months' notice, during which the names of offenders were not given, the pledge of publicity was redeemed. A long series of further analyses was published, with the full names and addresses of the vendors, the price of the coffee, the words of the advertisement claiming excellence, and the character of the adulterations. The daily press reprinted large portions of the articles, complimented THE LANCET upon its public spirit, and declared it to be the immediate duty of the legislature to adopt effective measures against such frauds.

The method employed in dealing with the analysis of coffee was followed in the analyses of other substances which appeared in the columns of THE LANCET during the next ten years; it will be sufficient to illustrate the work if no more than the bare results of the investigations are related. The second substance dealt with by the Analytical Sanitary Commission was sugar. Having described the macroscopic and microscopic appearances of sugar, both cane and grape, and detailed the foreign bodies—such as lime, lead, sawdust, starch, and acari—commonly found in impure specimens, the Commissioner gave the results of the examination of 36 brown sugars of different qualities and prices. Acari were present in 35 of the samples. Grape-sugar was detected in every sample, usually a proof of sophistication, for most of the sugars purported to be the much more powerful sweetening agent, cane-sugar. Stony particles or grit were observed in 11 samples, and woody fragments in 13. In four samples a variable quantity of flour had been introduced, evidently for the purpose of adulteration. Fifteen samples of lump sugar were then examined, and the results were found to compare very favourably with the results of the examination of moist sugar, for there were no acari, no grape-sugar, and no grit. Samples of moist sugar were then purchased in different parts of the metropolis, and every single one contained deleterious material, while two had been adulterated with flour.

The next article which fell under the Commission was arrowroot. The name "arrowroot" had been made, by dealers in the first place and in the second place by the general public, to cover almost every fecula bearing any resemblance to the true *Maranta arundinacea*, no matter how dissimilar the original plant might be. As a result there were several powdered substances in the market varying in price from a few pence to two or three shillings per pound, none of which was Maranta, but all of which had the valid claim of custom to the appellation "arrowroot." The Commissioner decided to get over this confusion by stating in his analyses the name of the plant from which the arrowroot was derived, to which end he examined specimens under the following names: Maranta arrowroot; Manihot arrowroot, or tapioca; Tacca arrowroot, a pulped tuber from Otaheite; Curcuma arrowroot; Arum arrowroot, the tubers of cuckoo-pint; and British or potato arrowroot, which was, frankly, potato-meal. The adulterations to which arrowroot was found to be commonly subjected were (1) the mixing of other tubers in varying proportions with true Maranta, (2) the substitution of an inferior for a superior root, or (3) the addition to one of the genuine "arrowroots" of some fecula not generally recognised as arrowroot at all. The most common sophistication in the trade was the addition to the genuine Jamaica arrowroot or Maranta root of potato-flour or tapioca in varying proportions. A second form of adulteration was the substitution of sago or potato-meal for Maranta. A third was the addition of potato-flour to an inferior root such as tapioca. The net result of the examination of 50 samples differing in quality, price, and appearance was instructive. Of the first 17 samples, all high-priced arrowroots varying from 1*s*. 8*d*. to 3*s*. 6*d*. per pound, 10 were found to be unadulterated and seven adulterated, four to an extreme extent. Of the next 28 samples of lowly-priced arrowroots, varying from 1*s*. to 1*s*. 6*d*. per pound, 17 were found to be unadulterated and 11 adulterated, five of the latter very grossly. In one of these adulterated specimens a few grains of the genuine Maranta arrowroot were detected by the microscope, but three samples consisted of a mixture of potato-meal and sago-flour, while a fourth proved to be potato-meal only. The last five samples were articles sold in canisters which bore the dealer's warranty setting forth the very superior and unusual quality of the article and challenging observation and scrutiny. Of these one was marked "Superfine West India Arrowroot, Warranted Genuine"; this was heavily charged with potato-flour. A second was "Recommended by the Faculty" as the most nourishing of all foods for children and invalids; this was entirely tapioca save a few grains of Maranta arrowroot. A third was "Warranted Free from Adulteration" and was merely potato-flour. The fourth and fifth were labelled "Arrowroot" and consisted of nothing but potato-flour.

Pepper next engaged the Commissioner's attention, with the result that he discovered that more than half the pepper purchased previously to certain convictions secured by the Excise officer was adulterated, but that subsequently to the enforcement of the law by the Excise authorities with regard to this particular condiment adulteration in an extensive form had ceased—a remarkable example of the practical effect of a little of the legislative interference which it was the chief aim of the Analytical Sanitary Commission to make general.

The next inquiry was larger in scope and of a different character. Its subject was the water-supply of London, and it was conducted in an uncompromising manner. The nature of the various impurities of water was first explained, and the action of the reservoir or cistern in favouring such impurities was discussed. A number of experiments were recorded dealing with the action of water on lead and iron, and the sources of the London water-supply at that date were investigated. The summary of the investigation ran as follows: "The waters at present in use in this metropolis are all hard, and have all the disadvantages of hard waters. They are, moreover, river waters, and for the most part contaminated to a great extent with organic matter, dead and living; add to these points their further deterioration by contact with lead cisterns and by the accumulation and growth of animal and vegetable productions which take place in these receptacles, and the case is proved against the whole of the present supplies of the metropolis." The metropolis to-day possesses an unrivalled water-supply, and the learning and activity which have brought this about have been regularly chronicled in the pages of THE LANCET from the day of the first indictment to the present era of great accomplishment.

From big to little, the next investigation concerned mustard. Here the Commissioner succeeded in demonstrating that genuine mustard, whatever the price paid, was hardly to be obtained in the year 1851. Of 42 samples submitted to examination every one was adulterated, and in every case the adulteration was the same in kind, varying only in degree, and consisted of the admixture of wheat-flour and turmeric as a colouring agent.

Bread came next, and formed the subject of a thorough investigation. The first report dealt merely with the chief constituents of bread as made from wheat, barley, oat, rye, rice, or Indian corn flour. The diseases of cereal grasses were detailed and the microscopic appearances of ergot and the different smuts, rusts, and mildews were described. Next the results of the chemical and microscopical examination of 44 samples of wheat-flour purchased from different corn-chandlers and bakers residing in the metropolis were given, to show that in no instance was there any other farina than wheat observed. This satisfactory result was attributed to the repeal of the Corn Laws, but it also pointed to the fact that the millers and corn-dealers were honest folk and that the bakers must be considered to bear the responsibility for anything other than wheat-flour found in bread. Twenty-four samples of bread having been purchased at random at the establishments of bakers in the metropolis, the result of examination was that every sample was found to be adulterated with alum.

Cocoa was analysed on precisely similar lines to those employed when dealing with coffee, and the result was that of 56 samples examined, many of which were warranted pure and possessing all sorts and kinds of charming qualities, eight only were found to be genuine. Sugar was present in 43 samples, its amount varying from 5 almost to 50 per cent., and starch was found in 46 samples, its amount varying also from 5 to 50 per cent. The starch was derived from wheat-flour, potato-flour, sago-flour, or a mixture of these in varying proportions.

Passing over the inquiries made into the purity of opium, tobacco, and certain invalid foods as being hardly germane to the inquisition held upon foodstuffs of the people, we come to tea. Tea formed the subject of a very lengthy and exhaustive examination. The leaves of the common willow, oak, sloe, hawthorn, elder, beech, elm, and an inferior sort of camellia were depicted side by side with illustrations of the genuine leaf of the tea-plant. Thirty-five samples of black tea bought at random in London shops were then analysed. Out of this ordeal the popular beverage emerged satisfactorily by comparison with the results found in the cases of coffee, arrowroot, and cocoa. In all 35 samples no other leaves but those of genuine tea were found. Twenty-three only, however, were perfectly pure, 12 having been treated with black-lead, indigo, turmeric, and mica, these last iridescent particles being added to give a sort of glaze to the leaves. No grosser adulterations were detected, but lest these reassuring results should blind the public to the possibility of the same being practised an account was added of the trial, instigated by the Excise, of a man and his wife for the manufacture of spurious tea. In this case the inspector under the Excise Act found the prisoners on premises at Clerkenwell with an extensive furnace installed in one of the rooms. Before this was suspended an iron pan containing sloe-leaves and "spent" tea-leaves, which had been purchased from coffee-shop keepers. On searching the place an immense quantity of these spent tea-leaves and bay-leaves were found, as well as every description of ingredient likely to be employed for the purpose of illicit manufacturing of tea—such, for example, as gum, copperas, and blacklead. There was a very large quantity of spurious tea in the room which well simulated genuine tea, and in another room 100 lb. of re-dried tea-leaves, bay-leaves, and sloe-leaves were spread out to dry. The practices revealed in this case were commoner, THE LANCET Commissioner considered, than would appear probable by the results of his analyses. There was, indeed, considerable evidence that the fabrication of tea was extensively practised, spent leaves being the chief stock-in-trade, when treatment with gum and mica gave "richness and bloom" to the appearance of the mess, and sulphate of iron was added to make the decoction astringent. Chestnut-leaves and sloe- and bay-leaves were occasionally used to give bulk. In the course of this investigation, it may be added, 20 specimens of green tea were examined, when it was found that the whole of them were artificially coloured.

In 26 samples of milk, 14 were adulterated, the addition being simply water. It was not found that any more complicated form of adulteration was practised, such as the simulation of creaminess by colouring matter or the addition of thickening substances, though these manœuvres were not unknown. Isinglass and gelatin were examined, with the result that each was found to be sold to the public for the other, in spite of the fact that they possess different qualities and that as a rule isinglass is better than gelatin. Thirty-three samples of vinegar were examined and the amount of acetic acid contained in them was found only in 23 cases to reach the standard laid down by THE LANCET as necessary to constitute a good vinegar. The addition of 1 part in 1000 of sulphuric acid was permitted by law, but many of the specimens exceeded the legal limit in this direction.

Spices next engaged the attention of the Commissioner, and out of 21 samples of ground ginger 15 were found to be adulterated, the substances detected being sago-flour, potato-starch, wheat-flour, ground rice, cayenne pepper, mustard husks, turmeric, or any combination of these. In whole cinnamon, of 12 samples seven were found genuine, while the other five were examples, not of adulteration, but of calm substitution, for in each case the thing sold as cinnamon proved to be the vastly cheaper cassia. In powdered cinnamon, of 20 samples six were genuine; three consisted entirely of cassia and 10 were adulterated with baked wheat-flour, sago-flour, and arrowroot. It is significant to note from Maculloch's Commercial Dictionary that the heavy duty on cinnamon caused the consumption of cassia in the United Kingdom to rise to treble its former amount between the years 1820 and 1840. Examination of 18 samples of nutmegs, despite fables of Yankee astuteness in manufacture, showed them all to be genuine. Mace, cloves, and allspice came out of the ordeal in a similarly handsome manner. Of 21 curry powders 19 contained ground rice, flour, salt, and colouring matter—red lead, for example—in varying proportions. Thirty-four samples of bottled fruits and vegetables were all artificially coloured with copper. Of 28 samples of anchovies seven were not anchovies at all, two contained some genuine among the spurious fish, while the brine of 23 samples was charged with Armenian bole or Venetian red. Various potted meats and fish and sauces were examined, and in many of them colouring matter was found to have been introduced. Of 35 samples of preserves and jellies 33 were found to contain copper, but it was suggested that the copper saucepans in which they were prepared were responsible for this.

Many of these examinations—for example, those on such important commodities as coffee and bread —were repeated from time to time, and their results as given showed that matters greatly improved in London after the revelations of THE LANCET Commission. In 1857 the investigation was carried into certain provincial towns. Among others, Birmingham, Manchester, Liverpool, and Leeds were visited, and the results of investigations in these cities led to the conclusion that London was worse supplied with the necessities of life than the large provincial towns; but in 1858 adulteration did not exist to more than one-tenth the extent that it had done at the opening of the Commission. Despite the success of his undertaking, however, the Editor of THE LANCET declared that he had no intention of abandoning the subject until effective legislation had been secured.

He had not long to wait, and THE LANCET Commission was a prelude to all our present laws in respect to the adulteration of food. The popular excitement created by the revelations of the Commission transcended even Wakley's enthusiastic expectations and made legislation against such abuses a matter of immediate importance. A Select Parliamentary Committee was appointed, and examined as far as possible all those likely to have any familiarity with the known adulterations, the methods necessary to detect them, their injury to public health, and their effect on the national revenue. The evidence given before this Select Committee confirmed the researches of THE LANCET Commission, not only in spirit, but in detail, and as a result the first general Adulteration Act was drafted and became law in 1860. This is known as Scholefield's Act. Its first section enacted that every person knowingly selling food or drink mixed with any ingredients injurious to health, and every person selling as pure any article of food or drink which is adulterated, should for every such offence on summary conviction pay a penalty not exceeding £5 with costs. THE LANCET was but moderately satisfied with this Act. The measure dealt with adulteration in but one of its aspects—namely, as it affected health. It did not touch upon the broader question of fraud. It was doubted if the small pecuniary penalties proposed to be inflicted by the Act would be deterrent, and it was pointed out that the appointment of analysts was left entirely optional. As the district boards and town councils empowered to make the appointments were largely composed of the very class of tradesmen who were the chief gainers from the practice of adulteration, it appeared probable the power would not be used. Future legislation, said the original Wakley, was imperative, and his words were confirmed some ten years after his death, during the whole of which time James Wakley and his brother, Thomas Henry Wakley, now proprietors of the paper, worked unceasingly to that end.

A second Act was passed in 1872. A second Select Committee sat in 1874 to inquire into the working of the two Acts, Mr. Scholefield's and that of 1872, under which many technical difficulties had arisen, and the result of this second Committee was the Sale of Food and Drugs Acts of 1875 and 1879. All this train of legislation was the direct outcome of Wakley's Analytical Sanitary Commission, and the vigorous manner in which the father's work was furthered by his sons.

THE INFLUENCES OF RAILWAY TRAVELLING.

The idea of an Analytical Sanitary Commission soon developed into a desire to inquire into all and every circumstance or position where medicine was directly interested, and henceforth, under the title of Commissions, articles were written, the result of investigations by competent persons, upon widely differing manifestations of social activity and development. The subjects of these Commissions are enumerated later (see p. 760), when many of the reports had been issued and many were to follow, but to one of these reports we will here make full reference because it illustrates well how the columns of a medical paper, running for a century, form a comment on public health in its widest aspect at different periods during that century, thus illustrating the profound modifications of judgment which ensue on experience.

The railway and THE LANCET arrived in the world practically at the same time; although history narrates earlier experiments there was in the year 1825 in the world only one railway carriage built to convey passengers. It ran on the first railway between Stockton and Darlington and bore on its panels the motto "Periculum privatum, publica utilitas," the words selected by George Stephenson as best describing the purpose to be subserved. He foresaw, in his own words, "the day when railways would come to supersede almost all other modes of conveyance in this country and railroads become the great highways for the King and all his subjects." Although the old highways remained, his vision was accurate over a hundred years; it is only to-day that there are signs that the paramount influence of the railway will be modified and that the old highways will be adapted to newer modes of travelling. But he would be a bold person who attempted to imitate Stephenson's words of prophecy and foretell the story of travelling a hundred years hence.

The first words of Stephenson's classical motto were immediately challenged, for the most alarming pictures were put forth as to the injurious influences on public health which railway travelling must produce, and awful dangers were described as impending over rash adventurers who should thus risk their safety. The immense velocity of 20 miles an hour was said to be fraught with danger to the respiration, and Dr. Dionysius Lardner, the author of "The Cabinet Encyclopædia" and "The Steam Engine," stated that the carbonic acid generated by the fuel when passing through long tunnels would inevitably produce suffocation by the destruction of the atmosphere. Sir Anthony Carlisle, surgeon and art critic, and twice President of the Royal College of Surgeons of England, had stated that tunnels would expose healthy people to colds, catarrhs, and consumptions, while boiling and maiming would be an every-day occurrence, but on the whole our pages were signally free from these melancholy prophecies. The medical profession—those at any rate who were in actual practice, and not merely praising days gone by—were unable to endorse the view that either physical ills or nervous complications followed railway travelling, and it was not till 1862 that it was considered in THE LANCET that any matters had arisen worth discussing on the subject of railway travelling in its relation to public health. But in that year the question arose in several directions. It became the opinion of medical men that the important social changes attributable to railways, while they afforded to some the means of avoiding unhealthy environments and of obtaining more time to get through their work, were not without serious drawbacks. The greater facilities for transaction of business provided by rapid communications were, it was thought, producing a corresponding change in the habits of life, for while more time was devoted to work, measures to ensure vigorous physical health were neglected. With some 40 years of figures to rely upon, it could be shown that travel by rail was safe compared with travel by coach and carriage, but collisions directly attributed to the overworking of engine-drivers, signalmen, and guards, were always made the subject of comment in our columns when trustworthy details could be got.

In 1862, the year of the death of its founder, THE LANCET made a detailed inquiry into the influence of railway travelling on public health, and the report which was published was a very detailed review of all the circumstances. The portion of the report on the railway tracks was written by a well-known engineer, went closely into full details of the formation of the bed, the life of the rail, the weight of the carriages, and the methods taken to avoid vibration and oscillation. The different carriages of four selected lines—namely, the Great Northern, the South Eastern, the Eastern Counties, and the Great Western Railways, were described. Robert Angus Smith, the well-known chemist, pupil, and translator of Liebig, and an authority on the atmosphere of mines, dealt with their ventilation and temperature, affording, however, no solution of the dilemma that plenty of air may mean plenty of dust. C. J. Blasius Williams, one of the founders of the Brompton Hospital, and a leading authority on pulmonary disease, urged the great precautions that should be taken against chill. Forbes Benignus Winslow, the psychologist whose work led to much of our present procedure where the influence of insanity upon crime is in question, wrote at large on the cerebral effects and mental excitations of railway travelling.

A most important part of the Commission was an inquiry into the health of railway officials and elaborate comparisons were made between the English and French figures. The result of investigation among the servants of the chosen companies convinced the representatives of THE LANCET that, while to be an efficient railway servant required a sound and healthy constitution, those who best satisfied such a test were those among whom the highest rates of sickness prevailed, the suggestion being that the more mentally developed were the most subject to shocks.

All the way through the inquiry it is clear that the Commissioners were themselves imbued to some extent with the public view, even while refusing to acquiesce in it, that there was something about railway management and even about railway travelling which required self-control. We find Brown-Séquard and Russell Reynolds, leading neurologists of the day, and distinguished alike for their clinical and literary work, consider railway travelling to be especially contra-indicated "where there is a tendency to softening of the brain," while Ernest Hart narrates a case of spinal anæsthesia induced by daily travelling, and White Cooper, surgeon oculist to the Queen, states that his daily experience convinced him that injurious consequences to the eyesight have followed the introduction of railway travelling. Other medical men warned the readers of THE LANCET of the effect of railway travelling on pregnant women, on sufferers from renal or vesical affections, from hepatic disease and dyspepsia. One of the last sections of the Commission deals with the question of railway spine, concerning which at the time there were no very definite opinions. It was not, indeed, till three or four years afterwards that Erichsen wrote authoritatively on the subject of "Concussion of the Spine," and to-day we are little clearer as to what was exactly meant by the condition. The various morbid conditions, however, which followed or were stated to follow railway accidents were called "railway spine" without any particular attempt to ascertain what, if any, organic changes had taken place, what were the real manifestations of traumatic hysteria, and how to draw the line between disease and malingering.

One of the main conclusions come to is that railways, though not offering anything like the dangers to life, limb, or general health which the public seem to have believed, and which many learned persons warned them would be the case, are none the less badly adapted to the requirements of passenger traffic. All the injurious influence clearly traceable to railway travelling appeared chiefly to arise from the inefficiency of the machinery for the work which it was intended to accomplish. A large number of suggestions are put out for keeping trains at equable temperature, providing air in hot weather and shelter in cold weather. It is pointed out that there should be ready communication between passengers and the guard, by which one may gather that communication cords had then not been established. Many of the instances of discomfort or injury are due to the fact that there was no lavatory provision, and a very definite warning is given to season-ticket holders, the class known to Americans under the convenient term of "Commuters":—

> "There are only two classes of persons especially likely to be injuriously affected by moderate railway journeys, even though frequent: they are persons advanced in life and of weakened power, and those who are subject to the special diseases which have already been studied in this relation. The actual exertion, the excitement, the mental strain, the peculiar influences of the motion of a railway carriage, indicate its dangers to those first mentioned. These constitute a small minority. But there are a number of persons who, although not far advanced in age, are yet the subjects of various conditions of ill-health depending on insidious degenerative disease of the brain and heart. The season-ticket holders of the railways are in large numbers men who have passed the best years of their life in hard and exhausting employment of mind and body. They are the successful merchants, the senior partners of flourishing firms, which they have built up by a life of labour; half-retired tradesmen, half-invalid bankers, *et id genus omne*. We can now see that it is by the injuries which have resulted to these men from their constant travelling to and from town that an impression has become current as to certain mischiefs which habitual travelling inflicts. When it is stated that such a banker, who comes up 50 miles three or four times a week, has to lie down half an hour before he can sign a cheque; that such a well-known chemist has suffered from symptoms of brain excitement since he bought his new house by the sea, and travelled daily to London; or that a certain barrister has found himself obliged to pay for his journey by epileptic seizures, the alarm soon extends beyond reasonable limits. But few men can endure without suffering

to travel fifty or a hundred miles daily to their business for any length of time. The influence of the journey itself is heightened by many accessory conditions to which we have adverted, and the present construction of the rails and carriages is such as to deprive the traveller of all those mitigations by which his discomfort might be diminished and his health safeguarded."

No doubt the great improvements which soon followed, and which were acknowledged in some places to have been stimulated by our report, did remove genuine sources of physical damage to the class especially in question; but no doubt, also, some of these grim accompaniments of railway travelling, even in its more primitive form, were imaginary. Either or both these things are indicated by the fact that the second Thomas Wakley came up to his office from Brighton, returning the same day, over long periods of time, until he was well over eighty years of age. Two years after the report was published the murder of Briggs by Muller in a railway train led to a public outcry for the provision of communication cords.

THE SECOND EDITOR.

SUCH were a few salient features of THE LANCET when Thomas Wakley senior died and when his youngest son, James Wakley, became in name, what he had been for some years in fact, the editor-in-chief of the paper.

James G. Wakley was born in 1825, educated at University College School, and took the diploma of M.R.C.S. in 1849, becoming M.D. of the University of Aberdeen three years later. He never engaged in medical practice, but almost immediately became his father's editorial assistant, and was shortly entrusted with a large share of editorial responsibility. Upon his father's death he became joint proprietor of THE LANCET, with his elder brother, Thomas Henry Wakley, who was at that time practising as a consulting surgeon, but who shortly retired from practice to become manager of the paper. The chief scientific advisers of THE LANCET were at this time Brudenell Carter, Francis Edmund Anstie, Christopher Heath, Harry Leech, medical officer to the Port of London, and Tilbury Fox. Ernest Hart was sub-editor. (Fig. 27.)

James Wakley's characteristics as editor were very simple. He made no pretensions to great learning or to a deep acquaintance with science. He had an ample store of good sense, a rare insight into both professional and public opinion, promptness in making up his mind as to where the right lay, and courage in the course which was accordingly adopted. He was free from spiteful feeling, and was particularly desirous that the opinions and criticisms of the journal for which he was responsible, though often vigorously expressed, should not lead to the sort of quarrelling which had characterised so markedly the earliest issues of the paper. He had, however, an extremely warm temper, and the editorial room of THE LANCET was more than once the scene of a personal fracas, the fact that James Wakley was a notable boxer determining the issue of the conflict. Nevertheless he was a sensitive and even deeply religious man, and afterwards sincerely regretted such episodes.

The great features of the work of THE LANCET during the editorship of Dr. James Wakley, which terminated with his death in 1886, were those which might have been expected from such a man succeeding to such a heritage. He left the scientific side of medical affairs in the hands of his staff and devoted himself to extending the public functions of the paper in the widest way. Civilisation he saw teemed with questions having a medical bearing which could not be settled without the assistance of medical science, and the matters upon which he concentrated himself were especially the duties of the State to the sick poor, to those afflicted with infectious disease, and to the insane. He urged upon influential writers the necessity of exposing in his columns all conditions of employment which were attended with insanitary circumstances. He had in Hart a very able lieutenant.

Ernest Hart, then quite a young man, after a successful career at the City of London School and St. George's Hospital, showed alike his ability and wide range of thinking in his duties at THE LANCET. He was attached to the ophthalmological department at St. Mary's Hospital, but his principal work for THE LANCET was to conduct, with Anstie and Dr. Carr, of Greenwich, an inquiry into the conditions of nursing in the Poor-law infirmaries, a development of the Analytical and Sanitary Commission. Ernest Hart did brilliant work for THE LANCET, but he was an ambitious man, and he considered that his services were not properly recognised by the designation of sub-editor, and the withholding from him of public credit. The relations between him and the rest of the staff became strained, and in the middle of the work started by THE LANCET on behalf of the sick poor in metropolitan workhouses he resigned and transferred his services immediately to the *British Medical Journal*, succeeding Markham as editor in 1866. It would serve no purpose, even if the material for absolute accuracy were forthcoming, to enter into the question of this quarrel, which, however, had an influence on the pages of both journals for a good many years. James Wakley and Ernest Hart lived for a considerable period on terms of open hatred, which were not softened by Hart's description of himself as late "co-editor" of THE LANCET. There were constant rumours of libel and even threats of violence. Two camps in the medical profession were formed, and while the protagonists grew careful in their personalities, each being aware of the other's prowess, their followers fomented the ill-feeling. It cannot, however, be said that the cause of medicine suffered, as those responsible for the conduct of each paper were so alert to get ahead of each other that they were stirred to efforts which gave excellent results for their readers.

Dr. Watkin William Jones, of Streatham Common, was an indefatigable assistant editor from 1870 until 1876.

WORKHOUSE ADMINISTRATION: ANSTIE'S WORK.

The inquiry into workhouse administration was the outcome of the senior Wakley's extreme dislike to the Poor Law Amendment Act of 1834, and we must return to the views of the father as dictating those of the son.

Till 1834 the Poor Laws of England were mainly framed against vagrancy, "sturdy" mendicity, and "valiant" pauperism—practically, the laws had not been altered since Tudor days. In 1832 a Commission of Inquiry was appointed to report upon the whole subject, inasmuch as it was suggested that the pauper was considerably better off than many men in employ. Outdoor relief was found, upon examination, to be subject to all sorts of fraudulent claims, and so far popular belief was justified; indoor relief was open to the charge of bad administration. The report of the Commission showed new legislation to be urgently needed, and an Act was passed which abolished outdoor relief except as medical attendance, and established a uniform method of administration for indoor relief through the workhouses. The "unions," as the units of grouping were termed, followed and swept away old landmarks in the country. Undoubtedly the first and striking result of the new Act was to transform a large number of paupers into self-supporting labourers, and some parishes were relieved of ruinous rates. But on the other hand, the poor in many districts suffered from the working of the Act; the test of poverty was found to be too drastic, while in the workhouse, now become the only shelter for persons whose misfortunes had not been earned, as well as for the shiftless and dissolute, a routine too much resembling prison prevailed. On these grounds, widely held but only partially justified, Wakley was as vigorous an opponent of the Act as Dickens, but he was able to justify his strictures by finding that it proposed to deal unfairly with the medical profession. On ascertaining this, he could grasp no stick too heavy with which to beat it, and his desire to champion the cause of the poor was eternally kept alive by the feeling that all opposition to the Act meant assertion of the rights and status of medical men.

Wakley pointed out that there was no proper provision for the medical attendance so freely promised by the Act. The Act thus regarded seemed to be one of pure economy, designed to make the able-bodied work, to make those in full wages save against a rainy day, and to make the well-paid of a family help the ill-paid. In no case were those in good health to be assisted by the State save as a last resort. As a result the medical man became a very important factor in the working of the Act. It rested upon his decision whether an individual should be helped or should not, and the medical man was not to be paid properly. The care of the sick pauper in many places was thrown upon him in return for a pittance. As this became clear from the editorial letter-bag the indignation expressed in THE LANCET at the regulations for medical attendance spread to the whole Act, and the early denunciations of its working must be taken to represent particular resentment of the sweating of medical men as much as general sympathy with the poor and down-trodden. The paper began to concentrate upon the treatment meted out to the Poor-law medical officer, and here was close on the heels of the great reproach under which the working of the new Act lay—namely, that the provision for the sick poor was totally inadequate. These persons, whose poverty was largely undeserved, were subjected to prison treatment conceived in an ignorant and barbarous spirit, and if the ideas expressed in our columns became a little less sweeping as time went on, and the humanitarianism of the views not quite so wholesale, the existence of a real scandal in the working of the Act became none the less apparent. The main scandal was the fact that the workhouses were badly built, badly administered, death-traps to those admitted, and foci of disease to those without.

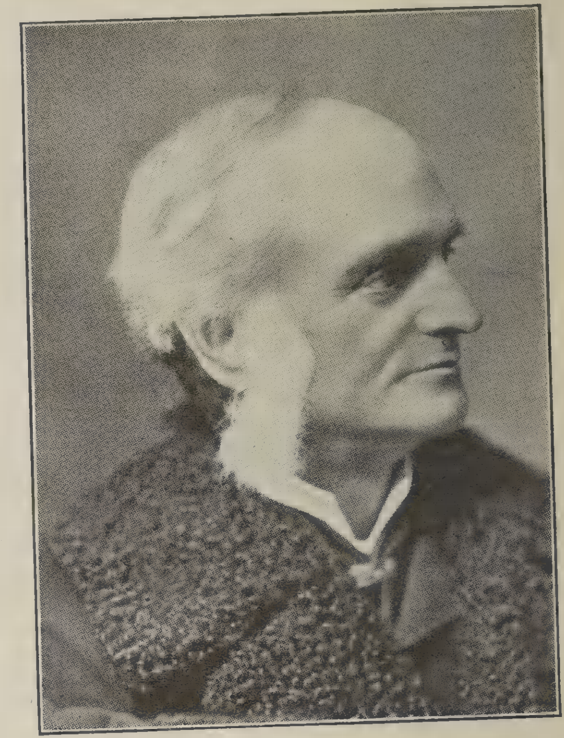

FIG. 27.—ERNEST HART.

James Wakley considered it a legacy from his father to make a complete investigation into the treatment of the sick poor in workhouses. When, therefore, two tragedies in rapid succession—one occurring in December, 1864, and the other early in 1865—called the attention of the public to this very topic in an urgent and even heart-rending manner, he seized on the opportunity to institute an inquiry on the general pattern of the Analytical Sanitary Commission, appointing F. E. Anstie, William Carr, and Ernest Hart to make the investigations. Carr was a highly endowed and energetic man, and as "Carr of Blackheath" was well known far outside his circle. He was one of the most prominent supporters at its start of Epsom College.

Francis Edmond Anstie was certainly one of the most valuable advisers and auxiliaries that THE LANCET ever possessed. His first appearance in London was as an anæsthetist, but in 1859, having been admitted a Member of the Royal College of Physicians of London, he went into practice as a physician, became assistant physician to the Westminster Hospital, and joined the staff of THE LANCET, where he proved a learned and sound editorial writer on all questions of public health, as well as a pioneer along certain paths of neurology. When in 1864 the conditions, sanitary and other, of Poor-law infirmaries led to THE LANCET inquisition, Anstie took the largest part in examining the London infirmaries and wrote the exhaustive report which appeared in THE LANCET of July 1st, 1865. The report was a forcible and clear document, moderation being especially shown in the method of its presentation, for while the general character of the buildings of the 37 institutions was fairly summarised, the population served being in each case given, and while the character of the separate wards and the system of the nursing were thoroughly analysed, there were neither sweeping allotments of blame nor allegations of callousness. Regrettable facts were allowed to speak for themselves. But the fairness of the report is shown most by the fact that it closes with the expressed intention of proceeding in future inquiries to describe briefly particular institutions which "will establish the propriety of the general conclusions and recommendations." These were as follows :—

1. With regard to the building accommodation provided for the sick, the London workhouses may be arranged in three classes, as stated in the body of the report—(1) A class in which the accommodation is irremediably bad, and in which the buildings ought to be altogether abandoned. (2) A class in which, with certain alterations, the buildings might be retained for the treatment of chronic disease and infirmity. (3) A class in which the buildings are capable of being developed into really good hospitals for the treatment of all kinds of disease. In *all* the infirmaries there are great defects as to classification and separation.

2. With regard to the wards, it may be stated that their ventilation is in all cases imperfect, from a deficient allowance of cubic space per bed, and that in many cases this evil is aggravated by essential faults in the construction of the buildings. In a large number of cases their lighting is imperfect. The water-closets, bathrooms, and lavatories are in nearly all cases insufficient, in many very decidedly so. The arrangements for washing the bedridden are nearly always insufficient. The ward management is in most cases insufficient, in many grossly so, owing to the want of good supervision. The bedding and other arrangements for the comfort of patients are inadequate in all but a few instances.

3. The system of nursing is nowhere perfect, and where only few, or no, paid nurses are employed, leads to the bad ward management already noted. Very few indeed of the pauper nurses are qualified for their work.

4. With few exceptions, the quality of the provisions, wines, &c., is good. Greater provision ought to be made for *variety of cookery*, and separate infirmary kitchens should be established.

5. With regard to the diet of the able-bodied, we have at present only to note the fact that there are great differences between the nutritive value in different houses, and to recommend the enforcement of a uniform dietary. The diets of the sick and the extras allowed appear to us liberal. The infirm and chronic patients decidedly require a diet of their own, similar in character to that adopted at the Strand Union, and which they should receive without the necessity of detailed orders from the medical officer.

6. The medical officers are over-burdened with work in nearly all cases. They should be at once relieved of all expenses on the score of drugs and appliances, and of the labour of dispensing drugs. They should be placed on such a footing as to ensure the absence of all interference by the master or matron with their arrangements for the sick, be better paid, appointed for life, &c.

7. With regard to the prevention of epidemic disease, it is highly desirable that there should be wards isolated from the body of the infirmary for the reception of fevers, &c.

FIG. 27A.—FRANCIS EDMOND ANSTIE.

Anstie continued the work for three more years, and the reports will be found informing reading for a student of sociology; but in 1868 he became editor of the *Practitioner*, which had just been started in the particular interest of scientific therapeutics, and although he continued to write for THE LANCET until the day of his death, he took no more part in the editorial management. His death was a tragedy, and occurred at the age of 41 from a wound incurred at a post-mortem examination while he was investigating some obscure cases of peritonitis which had occurred in certain charity schools. He was a martyr to science, whose work had issue in constructive legislation. For his report to our columns on the state of Farnham workhouse led directly to a Government inquiry and proved the starting-point of wide and real reform. In the articles on the Farnham workhouse THE LANCET took the gloves off, holding that the report on metropolitan workhouses, published two years previously, had constituted a warning which had been entirely neglected. The Government inquiry, conducted by two Poor-law inspectors, was protracted, but when their report came it proved to be in the main a justification of Anstie's accounts and the editorial comments upon them. The Government report admitted that the majority of the things brought forward in THE LANCET required the special attention of the guardians, and immediate reforms followed.

JAMES WAKLEY'S STAFF.

It has been indicated that James Wakley was particularly dependent on his staff for the details of medical journalism, whether those were concerned with scientific work or with public affairs. Unlike his elder brother he had held no hospital appointments, and unlike his father he had made no entry whatever into public life. He was never seen at any medical or public function, and, indeed, save by a few intimates, was hardly known by sight. He depended greatly upon his friends, was naturally slow to choose them, but when chosen they were trusted entirely. It is right, therefore, to say a few words concerning three of his well-known collaborators who, as far as internal administration of the paper was concerned, were even more closely associated with us than was Anstie. They were William Tilbury Fox, the famous dermatologist, Harry Leach, the friend of the Mercantile Marine, Christopher Heath, and Robert Brudenell Carter, well known as ophthalmologist, writer, and man of affairs.

Four Well-known Collaborators.

William Tilbury Fox, after a brilliant career at University College, London, began life as a general practitioner in the West End. Later he travelled in the East and, having taken up the subject of skin diseases, became dermatologist to the University College Hospital, resigning a big gynæcological appointment. This was in 1866, and from that time forward until his untimely death in 1879, at the age of 43, he was a regular editorial writer on the staff, and a man to whose general opinions on professional matters great respect was paid. He was so intimately aware of the methods and ideals which characterised the paper that during an absence of James Wakley through illness he was appointed temporary editor, a post which he held for nearly a year. His training and experience had given him a wide range of exact knowledge, and he was keenly interested in all questions of medical progress and reform. But as a member of the Convocation of the University of London he showed himself an energetic opponent of the proposal to admit women to degrees, and in this direction at one time he influenced the policy of The Lancet.

Dr. Harry Leach, like Dr. Tilbury Fox, died at the age of 43. His medical career and his association with The Lancet were largely determined by the fact that his first professional appointment was that of resident physician to the Dreadnought Hospital for Seamen. He proceeded immediately to use the opportunity and material in a close study of scurvy and dysentery among merchant seamen, and he wrote forcible articles on these subjects, which attracted notice in high quarters. The necessity of legislation was admitted, and in the autumn of 1868 the Merchant Shipping Bill was read "to provide effectually for the inspection of antiscorbutics," in which many other measures suggested by Leach, in our columns and in lay papers, for the benefit of the Merchant Marine found expression. Leach was also the author of many of the numerous articles which appeared in The Lancet describing the incidence of cholera in 1866, and both in practice and with his pen was a pioneer of preventive medicine. In 1870 he was appointed principal medical officer of the Greenwich Hospital, a post which he resigned three years later on his election by the Corporation of London to fill the post just created of port medical officer. Leach's work in The Lancet was valuable, therefore, in many directions. He described at first hand methods to be taken against dangerous epidemics; he was an authority on scurvy who was undertaking investigations for the Board of Trade; he wrote a useful medical guide for ships' captains; and in his post as port medical officer he became familiar also with the problems presented by the drainage of the Thames Valley and the water-supply of the metropolis.

It will be seen that of the five chief scientific advisers with whose help James Wakley began his editorship, three—Anstie, Leach, and Fox—all died as quite young men. But Carter lived till over 90 years of age. Robert Brudenell Carter was a general practitioner who in 1854 went to serve in the Turkish Army, and from the spot contributed letters to the *Times* and to The Lancet, summarising his Crimean experiences. He did not come to London until some 14 years later, but he remained a frequent contributor to our columns. He was not successful or happy in a provincial town, but with great resolution decided to obtain the F.R.C.S. before attempting to practise in London the specialty which attracted him. At this point let him tell his own story in a letter addressed to our columns:—

> "My life generally is calculated to encourage hopefulness under adverse circumstances. Up to the age of 40 I was a conspicuously unsuccessful general practitioner in the country. In my forty-first year I decided to burn my very small and shallow boats and to come to London. Within a year I was a leader writer for the *Times*, a constant contributor to the editorial columns of The Lancet, and surgeon to the Royal South London Ophthalmic Hospital. Within two years I was ophthalmic surgeon to St. George's Hospital and my way was fairly clear."

Carter's life is chronicled in a book, "Doctors and Their Work," which is full of good and useful things, but which was written late in life and does not display him as the literary master that he certainly was through some 50 years of his prolonged life. Eloquent, incisive, and bitter with the pen, he could speak in public with the same command of language and high level of style. James Wakley relied on Carter almost too much, and the paper became involved in disputes upon personal matters which damaged its reputation for fairness. He left the staff of The Lancet as the result of some violent articles which he could not justify. Those who remember Carter's work for 20 years on the General Medical Council will recall the many opportunities which his incisive and aggressive speaking gave for quarrels. In debates such things can be adjusted at once, misunderstandings cleared up, and charges rebutted, when no permanent harm follows, but in newspapers immediate reply is impossible.

Over Twenty Years' Work in Gland Therapy

gives us confidence in recommending for special attention the following Products which have now stood the test of extensive clinical experience.

HORMOTONE

Menstrual and Menopausal Disorders

"I have used Hormotone in one case of obstinate amenorrhœa of four years' standing—a month's use of the tablets resulted in a period."

TRYPSOGEN

Diabetes Mellitus

"I have used your Trypsogen for many years in cases of diabetes and find nothing equals it. It enables the patient to take more liberally of starchy food without detriment."

SECRETOGEN

Gastro-Intestinal Disorders

"I have used the Secretogen for many months and have found it most beneficial in many conditions such as chronic constipation, summer diarrhœa, and intestinal toxæmia."

KINAZYME

Malnutrition and Wasting

"A child of 10 months gaining only 8 ozs. in four weeks gained 1 lb. 6½ ozs. the four following weeks on two tablets of Kinazyme per day."

COMPLETE LITERATURE AND A COPY OF "THE JOURNAL OF ORGANOTHERAPY" WILL BE SENT FREE AND POST PAID TO MEMBERS OF THE MEDICAL PROFESSION.

G. W. CARNRICK CO.

NEW YORK.

London Agents: AMERICAN DRUG SUPPLY CO., LTD., 40-42, Lexington Street, W. 1.

Fosfoxyl. Fosfoxyl.

Fosfoxyl.

Fosfoxyl acts as a powerful stimulant of the central nervous system and promotes mental activity ; its particular action in melancholia and neurasthenia is due to its property of elevating the nerve tone.

PILULES.

Four pilules contain 1 cgm. pure, active, assimilable phosphorus.

Dose :—Two pilules three or four times a day.

In boxes of 60 pilules.

LIQUID.

Two teaspoonfuls contain 1 cgm. pure, active, assimilable phosphorus.

Dose :–One teaspoonful three or four times a day.

In bottles of 5½ oz.

EXCITANT OF ASSIMILATION

CORRECTIVE IN MALASSIMILATION

FOSFOXYL is for Nervous Depression as Digitalis is for that of the Heart.

Fosfoxyl. Fosfoxyl.

Carter left the paper as a sequel to one such episode, but rejoined 25 years later, when the present editor, who had been his pupil, consulted him on certain professional positions which were being much discussed before the General Medical Council, where Carter was sitting as the representative of the Society of Apothecaries. He immediately gave all possible assistance, and from that day until the last decade of his prolonged life he wrote occasional leading articles in The Lancet.

Christopher Heath, known to four generations of students as the author of "Minor Surgery," was a blunt forceful character. He was essentially good-hearted, but made enemies by these qualities. They were displayed in our columns on many occasions and led to awkward situations. But James Wakley recognised in him a powerful assistant, and he and Carter for some years exercised great influence over the paper.

By 1872 the staff of The Lancet had become considerably augmented; the size of the paper had increased with the enormous development of medical knowledge, making it necessary to have different writers able to give authoritative opinions on their special subjects. In addition to the names mentioned, the staff was now notably strengthened by Robert Barnes, James Peddie Steele, and Jeffrey Marston, while Sir John Tweedy, who at the time was only just qualified, was admitted to the councils of the paper. Dr. Thomas Buzzard, whose neurological work has placed him definitely among the pioneers of modern medicine, was also a much appreciated leader-writer, for he was a practised journalist, with a learned and graceful style. Later on, at different intervals, the staff was reinforced by Sir John Williams, Vivian Poore, Henry Power, Dr. Sidney Coupland, Pearce Gould, W. S. Greenfield, and John Curnow. Sir John Tweedy joined the staff immediately upon his qualification—indeed, to be accurate, his early contributions were actually written before he had obtained any diploma—and he undertook from the first a very difficult and delicate appointment, namely, to keep the readers of The Lancet informed upon matters connected with the Royal College of Surgeons of England, and surgical practice in the metropolitan hospitals.

CONTINUITY AND PROGRESSION.

THE scheme of work which James Wakley laid before his staff was twofold. He desired to continue and develop the undertakings of his father—an act of piety which was sometimes embarrassing; and he desired at the same time to keep his columns as open to new movements, scientific or professional, as they had been open during 40 years. This was well shown by the sequels to the Analytical Sanitary Commission, such, for example, as the inquiry into the conduct of lunatic asylums, and by the watchfulness maintained over the actions of the Royal corporations.

The Lancet and the Royal Corporations.

In 1872 the position of The Lancet with respect to the Royal College of Surgeons of England was not any longer one of open warfare; but the general feeling against the constitution of the College had not been abated by the institution in 1843 of the order of Fellows. In 1843 a new Charter was obtained for the College, under which there was instituted a class to be called the Fellows, from whom and by whom the Council was to be elected. The number of the Council was increased to 24, and while the existing members of the old Council were allowed to continue in office for life, provision was made that three elected members should retire annually, so that when no more life members were left it would not be possible for a member to retain his seat for a longer period than eight years without re-election. A further change was effected by this Charter, for it provided that the examiners had no longer to be selected from the Council, but any Fellow, whether on the Council or not, became eligible and for a term of not longer than four years. It will be seen that the Charter, therefore, did meet two of the main charges brought for so many years by The Lancet against the constitution of the College. Although the Council was only enlarged from 21 to 24 persons, it was no longer self-electing, and the old rule that ten out of this small Council must constitute the Court of Examiners was abolished.

The double reason for the creation of Fellows thus became apparent: the new class was to form an electoral college for the Council and also to provide men up to date in their work to carry on the examinational duties. The first body of Fellows was chosen arbitrarily, mainly from among the Members, but within one year from the date of the Charter the Fellowship was closed except by examination, the tests being graded to provide that the Fellows should show by practical and academic acquirements that they were fit men to conduct College affairs, and particularly to examine and train their juniors. The Lancet admitted that the new Charter stood for reforming principles, but found that it was none the less an unsatisfactory and undemocratic arrangement, in that the Council, while retaining all the power, would be recruited from a special body, in the first instance nominated by themselves, while no provision had been made for representation of the Members in general upon the governing body of their College. The higher standard of examination laid down for the Fellowship, it was allowed, provided the College immediately with a properly equipped body of examiners, and did away with the scandal caused by nonagenarians when found examining lads of the age of their grandchildren.

The College continued to come in for criticism also because of the privacy with which its business was transacted, although here the Royal College of Physicians of London was much more frequently and more logically attacked for its "*secreta collegii*." The College, as has been said, escaped the diatribes to which its sister College had to submit in the early issues of The Lancet, because it played so small a part in the life of the general practitioner. In Scotland especially, and to some extent in Ireland, it was more usual for the general practitioner to have obtained a medical degree, but in England a practitioner practised, as a rule, on his diploma from the College of Surgeons or his licence from the Society of Apothecaries. It was not till 1884 that an agreement was entered into by the Royal College of Physicians of London establishing a Conjoint Examination Board with the Royal College of Surgeons of England, and until that date the part played by the senior College in general practice was negligible. But officially the College of Physicians was of high importance, and its habit of keeping all its business, which was presumably discharged in the interests of the constituency and also of the public, entirely secret led to a good many caustic articles. One President, Sir George Burrows, made a definite attempt to intimidate The Lancet, to which James Wakley replied in characteristic style. Some information had been published in The Lancet, through a member of the staff, who wrote the article upon information from persons in authority who did not consider that the circumstances were private. The persons who gave the information on reconsideration believed that no question of privacy arose, and Sir George Burrows was told that the public apologies upon which he insisted would not be given. Succeeding Presidents were less susceptible to the dangers of publicity—indeed, from this time forward cordial relations existed between the College and the paper. (Fig. 28.)

Fig. 28.—Sir George Burrows.

In all the developments of medicine which have occurred during our existence it has been our aim to provide news and comment upon that news, to record all medical discoveries, to give space to the work of those who were engaged in promoting them, and to hold the balance between those who thought criticism to be criminal and those who thought that the world would be no better off for the new work. To give any summary of the forward movements which in their earlier forms originated in The Lancet, or were noticed in it, would be in considerable measure to give a summary of the journal from its issue until to-day. Certain prominent communications which marked the early years of the paper have been singled out for notice because they became important in the years which followed, owing to developments along the indicated lines. But we have now reached the era of the greatest medical events of the nineteenth century, which have revolutionised the whole of our science—namely, the discovery of bacteria, leading to the introduction of antisepsis, while we have passed by a discovery of nearly as high a therapeutic importance—namely, the introduction of anæsthetics. The way in which these great movements were received by the paper is a running comment upon its conduct over an extended period, and at these points the summary of our work is brought down to to-day.

ANÆSTHETICS.

Most things that were new in the medical world were being sent to The Lancet for publication at the time that the anæsthetic action of ether was revealed—especially was this the case with English or French work. The fact that something new was arriving would emerge from reports from institutions or from learned societies, when fuller information was at once solicited and obtained.

The news from Boston of W. T. G. Morton's successful administration of ether on Sept. 30th, 1846, in dental and surgical operations reached England in December of that year, when its practical importance was immediately tested and appreciated. In London, on Dec. 19th, James Robinson, in his dental consulting room, and on Dec. 21st Robert Liston, at University College Hospital, operated on patients under ether anæsthesia, and lost no time in chronicling their successes, the letter from Liston, published in The Lancet of Jan. 2nd, 1847, having been written *on the very day* of the operation.

That issue of the paper contains some other interesting documents relating to the early surgical operations performed during insensibility; they include, through the courtesy of Dr. Frank Boott, a paper read by H. J. Bigelow before a learned society in Boston, on Nov. 9th, 1846, describing the technique and discussing its application, and also a detailed description by Boott himself of the dental operation performed on Dec. 19th in his presence by Robinson. An editorial pronouncement in the same issue of The Lancet left no doubt of the fundamental importance of the discovery, the development in various branches of medicine and surgery of "this most valuable discovery " being foretold. An attempt to patent the discovery in the name of its alleged joint inventors, C. T. Jackson, a chemist, and Morton, was denounced as preposterous, if not legally impossible, in an editorial article a fortnight later. "The thing is far too noble to be clogged with a mere commercial transaction," said THE LANCET, which had been already able to chronicle the performance of operations under ether at five London and five provincial hospitals. Illustrations of different forms of apparatus for ether administration appear in nearly every issue of THE LANCET during the early months of 1847, one of the first being that devised by Dr. John Snow, whose subsequent researches into the physiology of inhalation anæsthesia, published largely in THE LANCET, formed a valuable addition to the early literature of the subject.

It will be convenient to give dated references to the communications alluded to. Under the general heading of " Operations without Pain," a series of special reports, with full details of cases, from hospitals throughout the country began in THE LANCET of Jan. 16th, 1847, and continued for 13 successive weeks. An elaborate questionnaire was prepared and addressed in April, 1847, by Thomas H. Wakley, the eldest son of the Editor and then surgeon to the Royal Free Hospital, to the surgeons of London hospitals, on the grounds that it was " high time the profession should be put in a position of authentic information relative to the action of a remedy which has already produced such an unparalleled influence in the practice of surgery in this country." The peculiar applicability of the new discovery to general surgery was early recognised in THE LANCET, but, even in January, 1847, attempts to employ it in medical cases, such as tetanus and rabies, were deprecated on physiological grounds. Its effects on surgical shock were discussed and its use in operative midwifery prophesied. The prophecy was even then being realised, for by February, 1847, ether was already in use in obstetric operations by Prof. J. Y. Simpson in Edinburgh, by Prof. E. W. Murphy in London, and by Baron Paul Du Bois in Paris. (See THE LANCET, 1847, i., 228 and 247.)

The unsuitability of ether for cases with bronchitis was being established by our contributors (1847, i., 1210) and resuscitation by means of oxygen (ibid., 371) was being practised, while on April 17th, 1847, we were able to record examples of the practical application of anæsthetics to jurisprudence, in distinguishing real from feigned disease.

The attitude of the Editor of THE LANCET, with regard to the rival claims springing up weekly for the honour of introducing the new weapon, was an eminently sane one. In a review (1847, i., 1284) of what was apparently the first book (by J. Robinson) to be published on the subject in this country, the issue was clearly stated. " Many persons have suggested certain sniffings and breathings, and have employed them in private in a few slight cases ; but these we may pass by as unworthy of notice—certainly not detracting in the least degree from the praise and honour due to the American originator, whether that originator be Dr. Morton, Dr. Jackson, or Mr. Horace Wells, the last claimant." A few weeks after this pronouncement we published documentary evidence substantiating the claim of Horace Wells for the use of nitrous oxide gas for tooth extraction prior to the work of Morton. At this time the name of Crawford Long, who apparently preceded Wells, was still unknown in this country.

Meanwhile, other gases came into use. In our foreign news columns, which incidentally gives evidence of service by well-informed correspondents in various centres of Europe, especially in Paris, we find a report (THE LANCET, 1847, i., 411) of a discussion at the Académie de Science, Paris, where Baron Flourens demonstrated that hydrochloric ether (ethyl chloride) had anæsthetic properties similar to those of ether. The next discovery recorded was a British one, and took the form of an original article published in THE LANCET of Nov. 20th, 1847, by Simpson (Fig. 29), on " A New Anæsthetic Agent More Efficient than Sulphuric Ether," followed three weeks later by details of nine obstetric operations under the said agent, known as chloroform. Prothero Smith and Murphy also recorded their experiences with chloroform in our columns in November and December, 1847.

While it was obviously much too soon to attempt to assess the relative merits or uses of the rival anæsthetics—and indeed this task has hardly yet been completed—editorial pronouncements at this period left no doubt that differences were already beginning to be recognised. In THE LANCET of Jan. 1st, 1848, Thomas H. Wakley was able to publish a record of 100 experiments on different animals performed by himself with ether and with chloroform, with the assistance of Erasmus Wilson, described as " one of the best physiologists of the day," and " that scientific and practical chemist, Mr. Bullock," in whose laboratory the drugs were manufactured. T. H. Wakley's conclusions, quoted again in an editorial comment on the first human death from chloroform, reported in our columns on Feb. 5th, 1847, was that "of the two agents in question assuredly the more dangerous of the two will be found in the vapour of chloroform."

This prophecy was indeed soon realised, and led to a reaction against the use of the newer drug in favour of ether. During the next 20 years the disadvantages of pure chloroform were made further manifest by many considered articles in THE LANCET, and in 1864 a committee of the Medico-Chirurgical Society was set up to consider the whole question from the physiological, therapeutical, and toxical standpoints. At this period we chronicled the fact that the resident anæsthetist was beginning to be an institution at the big teaching hospitals, and that " Mr. Clover's admirable apparatus," the first to register percentages of chloroform, was coming into general use, this apparatus being employed by the Medico-Chirurgical Society's committee in their investigations. The report is published substantially in THE LANCET

(1864, ii., 49 and 69) and the mixture of chloroform, alcohol, and ether (A.C.E.) recommended by the committee found favour till comparatively recent times, when the alcohol was eliminated and the C.E. mixture retained in common use. Meanwhile the use of pure ether was brought back into popularity by the introduction of Clover's inhaler. John Clover was a prolific inventor, and suggested the aspiration of the bladder after lithotrity years before Bigelow. His growing distaste for the administration of pure chloroform led him to experiment still further, and stimulated by the revival by G. Colton of the claims of nitrous oxide, he suggested in The Lancet (1875, i., 33) the use of nitrous oxide to precede ether, and later devised an apparatus to administer successively N_2O and ether. It was this Colton to whom Horace Wells originally owed his inspiration to use nitrous oxide in 1844. Twenty years afterwards Colton re-established the gas in fashion in Paris. In 1868 we had occasion to comment on a discussion of the properties of nitrous oxide at the Medical Society of London (which met even then on Mondays) and to describe a demonstration of its administration at St. Bartholomew's Hospital and at the Dental Hospital. Our comment was that while the agent as used for the process of extracting a tooth was certainly a success, the effects did not give rise to much expectation that the gas was at all likely to replace chloroform in any but the very shortest of operations. This view, indeed, proved correct, since not until 1899, after the publication in our columns by Sir Frederic Hewitt of a preliminary report on the anæsthesia produced by the administration of mixtures of nitrous oxide and oxygen, did the method come into general use for major operations, and not until the investigation of Crile and his school in the late nineties did it become really popular.

There was now, by the last quarter of the nineteenth century, a selection of anæsthetics to choose from, and it became desirable once again to attempt to estimate the physiology of anæsthesia with special reference to the toxicity of the individual substance used. A commission with this object was established by the British Medical Association, who issued a report in 1878, and two other commissions were financed by the Nizam of Hyderabad in the early nineties. In view of the extreme complication of our modern views on the physiology of anæsthesia, it is hardly surprising that these reports gave some contradictory results and were subjected to much criticism from physiological experts. It was left to The Lancet to revert to the clinical aspect, which had for the time being been rather lost in animal experimentation, and in the early months of 1893 we were able to publish the outcome of a special Lancet Commission appointed to investigate the subject of the administration of chloroform and other anæsthetics from the clinical standpoint.

The history of that investigation was as follows. In 1889 the Nizam of Hyderabad wrote to The Lancet through the surgeon at the Residency, the late Colonel Edward Lawrie, I.M.S., to ask that a representative of the paper should be sent out to repeat the experiments upon the administration of chloroform which had been performed by a committee appointed by His Highness's Government. The Nizam's Government placed the choice of a scientific man to repeat the experiments, and make any others that might suggest themselves, in the hands of The Lancet, and enclosed a fee of £1000, together with an invitation from the Government to be their guest in Hyderabad. Lauder Brunton was nominated, and he accepted the commission in the rather delicate circumstances that the work of the Hyderabad Committee had already come to certain conclusions with regard to the action of chloroform which were at variance with the views expressed by Brunton in his pharmacological writings. Brunton's contributions to The Lancet had been for many years frequent; indeed, since he delivered the Goulstonian Lectures on "Pharmacology in Relation to Therapeutics" he had regularly assisted us. All schemes in favour of national health, of school hygiene, or of proper military training had in him a stalwart advocate. In this last connexion his familiarity with the German professional world had led him for some years to believe that war between this country and Germany was inevitable, and from a letter published in The Lancet it came out that in days gone by Sir Douglas Haig and Brunton had discussed the circumstances of its occurrence. In the report of our Commission details of the cases were set out in tables under appropriate headings, and though the document was printed 30 years ago, the conclusions, which are set out fully below, would be substantially endorsed by expert opinion at this day. The conclusions were :—

1. That the death-rate under anæsthetics heretofore has been unduly high, and may by improved methods and greater care be lowered.

2. That ether, when properly given from an inhaler permitting graduation of the strength of the vapour, is the safest anæsthetic in temperate climates for general surgery.

3. That nitrous oxide gas should be employed for minor surgery and should replace chloroform in dental surgery.

4. That chloroform, when given by a carefully trained person, is a comparatively safe body, but is not in any case wholly devoid of risk.

5. That no age or nation is free from danger under anæsthetics.

6. That the perils of anæsthetics, however slight, demand that the undivided attention of a duly qualified and trained medical man should be given to the administration of the anæsthetic.

The work appeared in the columns of The Lancet in 1890, being edited with extraordinary care by Dr. Dudley Buxton, and was afterwards produced in volume form. It is interesting to note that whereas the scientific aspect of the subject was altered by the discovery of the occasionally delayed effects of chloroform poisoning, to which attention was first called in The Lancet (1894, i., 193) by Leonard Guthrie, the conclusions reached by this most exhaustive research into clinical records throughout the Empire over a long period of time by our Commission have been substantiated by subsequent experience.

Of more recent years the advances in general anæsthesia have been perhaps less striking. Early in this century W. T. McCardie revived interest in the anæsthetic properties of ethyl chloride by reporting first a few cases and then a series of over 600 under general anæsthesia induced by ethyl chloride, thus bringing to general notice in this country an anæsthetic which had hitherto been used chiefly abroad. Intratracheal ether was introduced in 1909, but did not come into general use in this country until a few years later. In a review of various methods and apparatus at the end of 1911 we quoted mainly American and foreign authorities, and were thus able to keep English workers in touch with a valuable technique.

In Europe scopolamine-morphine anæsthesia (twilight sleep) was also beginning to find favour in certain cases; its merits in labour were extolled by C. J. Gauss of Freiburg, and were discussed in THE LANCET by Dr. G. B. Buchanan in 1906. This method of producing *general* anæsthesia by means of the hypodermic syringe has advanced in efficiency and popularity, especially for ear, nose, and throat work, but the serious development of *local* anæsthesia was dependent on the perfection of the hypodermic syringe in 1853 by Alexander Woods. Local anæsthesia by means of surface applications was much older. In June, 1848, T. Nunneley, of Leeds, published in THE LANCET the results of attempts to use ether, chloroform, and certain other volatile drugs in this way, while a week or two later Simpson records in our columns a further series of experiments on the same lines. The production of local anæsthesia by means of cold was recorded by James Arnott in THE LANCET (1847, ii., 98 and 287), using ice and salt, but this method was only capable of a wide application after the invention of the ether spray by B. W. Richardson early in 1866. This was at once recognised by THE LANCET as a device whose "application would evidently be of the most valuable and beneficent utility."

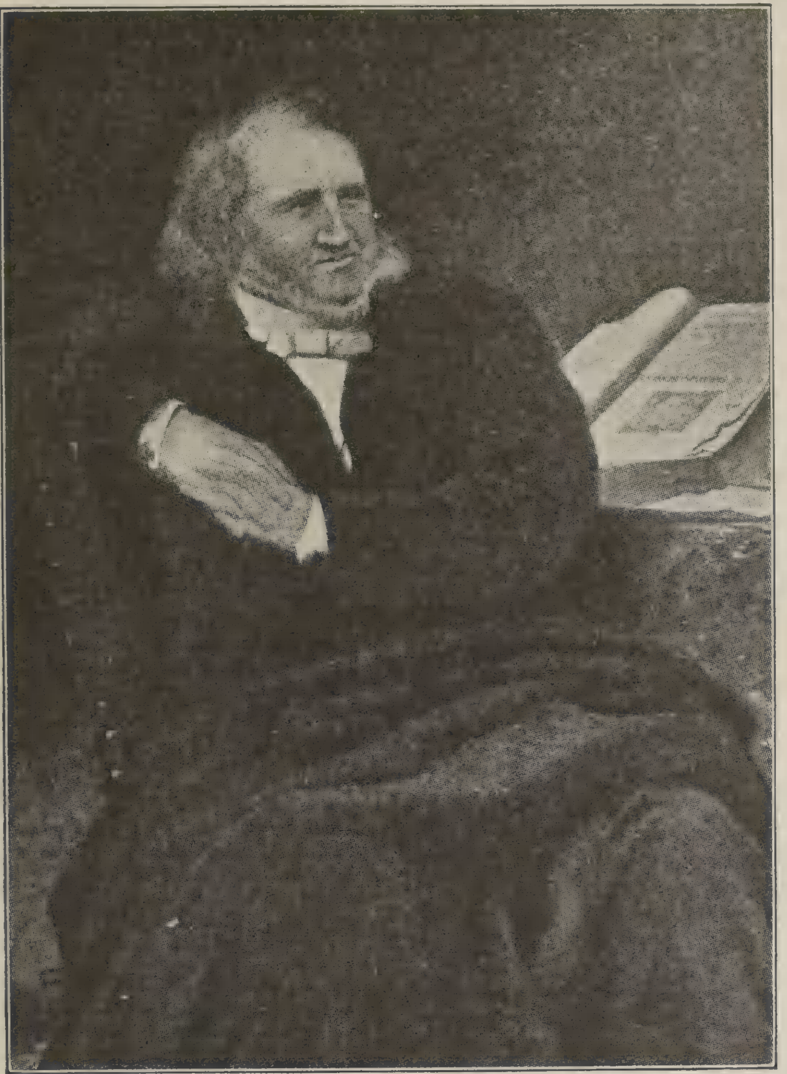

FIG. 29.—SIR JAMES Y. SIMPSON.

The discovery of cocaine in 1857 was the next landmark, but it was not until 1884 that Koller in Vienna used this drug in eye operations. Of this important event we received and published immediate information, and our readers were not slow to give the drug a trial. For the rest of the year (1884) our correspondence columns constantly recorded British experience of its uses, and, none too soon, of its dangers. In the last decade of the century less toxic derivatives of cocaine began to be substituted, and infiltration and spinal methods of anæsthesia were evolved. In THE LANCET (1901, i., 137) we reviewed the work of Bier, Corning, and Tuffier in spinal anæsthesia, and our foreign correspondents kept us well posted through the following years with developments in this art. The methods of Crile did not gain much attention in this country till early in 1913, when we published an elaborate article from his pen. His anoci-association theory tended somewhat to reconcile the two schools of anæsthetic practice, since he advocates spinal anæsthesia combined with inhalation of nitrous oxide. The last-named gas, combined with oxygen, proved peculiarly suitable for war surgery, and led to an extended use of this combination in civil practice. Of recent years advances in anæsthetics have been due rather to general improvement in technique than to any startling changes in drugs or procedure. The improved status of the modern anæsthetist, who is now in an increasing number of hospitals a valued member of the honorary staff, is a corollary of the development of the specialty. It is hardly necessary to add that we have always insisted on, and are even now again urging (see The Lancet, 1923, i., 910), the recognition of the anæsthetist as a most important member of the operating team, to whom more consideration should be given in the event of a fatality—now, happily, a rare occurrence—and more credit for his share in the common successful issue.

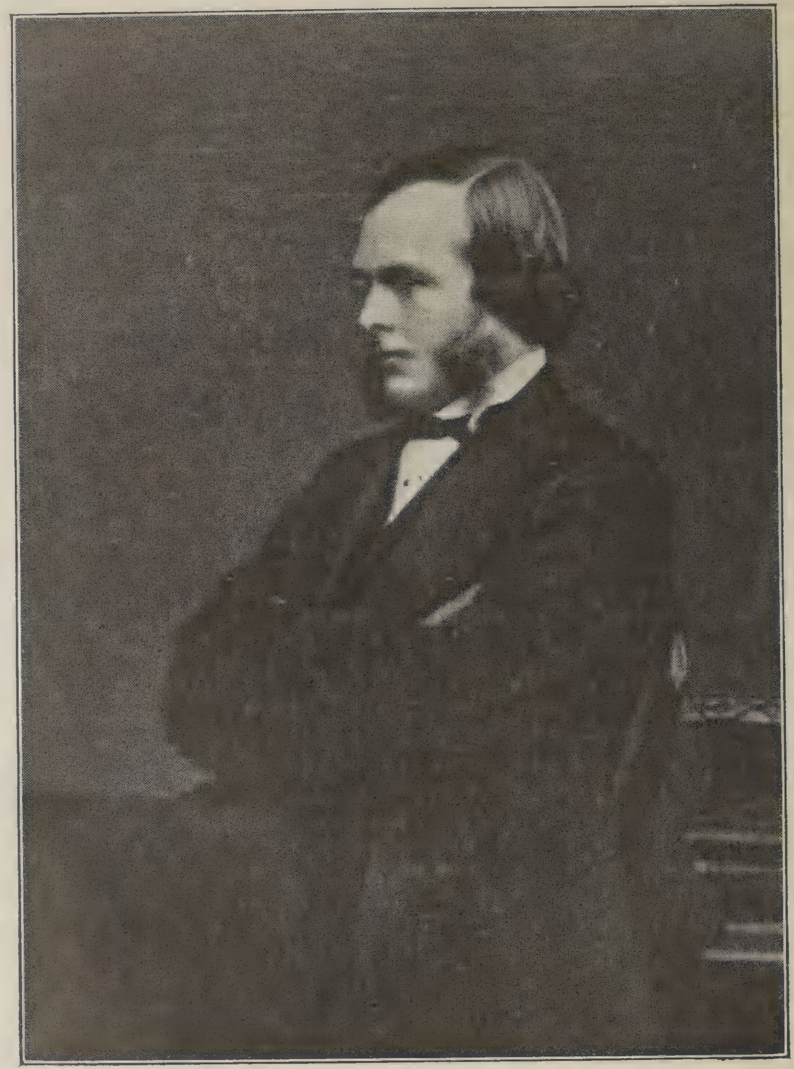

Fig. 30.—Joseph, Lord Lister.

THE FIGHT AGAINST BACTERIA.

Antiseptics.

The Lancet was the journal selected by Joseph Lister (Fig. 30) for the first publication, in 1867, of his method of treating wounds on antiseptic principles. It is almost impossible nowadays to realise the conditions of surgical practice before these principles were established. In the graphic words of Sir Hector Cameron: "Every wound discharged pus freely and putrefactive changes occurred in the discharges of all, producing in the atmosphere of every surgical ward, no matter how well ventilated, a fœtid sickening odour, which tried the student on his first introduction to surgical work just as much as the unaccustomed sights of the operating theatre. It is hardly necessary to add that fatal wounds, diseases, and complications were never absent at any time from the hospitals of that day."

The steps of Lister's life are well known. After a distinguished career as a student at University College Hospital he qualified in 1852 and served as house surgeon to John Erichsen (Fig. 31) in London, and later to James Syme (Fig. 32) in Edinburgh. He was elected successively to the chair of Surgery at Glasgow in 1860, to the professorship of Clinical Surgery in Edinburgh on the death of Syme in 1869, and to King's College, London, in a similar capacity from 1877 to 1893, when he retired from active practice, though he lived till 1912. It was during his years at Glasgow that the terrible after-results of surgical intervention, especially that conducted in hospitals, led to various drastic suggestions. These included (1) demolition of hospitals every two or three years, and (2) the treatment of patients in a constant draught—the current assumption being that it was the hospital atmosphere which led to the onset of redness, swelling, heat, and offensive suppuration and sloughing, if not actually pyæmia, which were almost the normal sequelæ of operations.

Lister described in The Lancet (1867, i., 326) how, pondering over "the frequency of disastrous consequences in compound fracture, contrasted with the complete immunity from danger to life or limb in simple fracture," and searching for the cause of the decomposition of living tissues exposed to the air without protection, he realised that "a flood of light has been thrown upon this most important subject by the philosophic researches of M. Pasteur, who has demonstrated by thoroughly convincing evidence that it is not to its oxygen or to any of its gaseous constituents that the air owes this property, but to minute particles suspended in it, which are the germs of various low forms of life." Applying Pasteur's discovery to the treatment of wounds, Lister concluded with admirable logic that "it appears that all that is required is to dress the wound with some material capable of killing these septic germs, provided that any substance can be found reliable for this purpose and not too potent or caustic." He continued by describing the reasons which had induced him in 1865 to choose carbolic acid as the antiseptic to be tried, its local sedative action being one of the reasons, and gave in this and four subsequent issues of THE LANCET detailed accounts of the cases of compound fractures, abscess, &c., in which he had successfully used this method—his restraint and absence of self-advertisement in what he rightly regarded as a most important innovation being noticeable. In the last of this series he described the application of his treatment to a case of psoas abscess in a woman, aged 25, explaining that "here the essential object is to guard against the introduction of particles from without, at the same time that a free exit is afforded to the constant discharge of the contents."

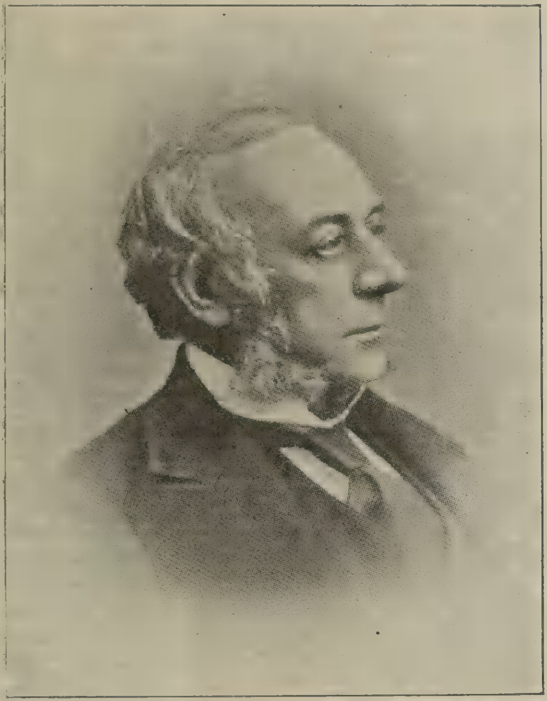

FIG. 31.—JOHN ERICHSEN.

We have quoted Lister's actual words in these papers, because in later controversies on his methods the real issues on which his treatment was based—in essentials the principles guiding surgery to-day—were overshadowed, and even Lister himself appears to have lost sight of them in the heat of defence. For example, he resented hotly the suggestion by Sir J. Y. Simpson (THE LANCET, 1867, ii., 546) and others that he was not the first to use carbolic acid in the treatment of wounds. Now it did not matter if he had been anticipated in the empirical use of carbolic acid as a dressing of wounds: of the principle guiding its choice he was the originator. Much more important than the previous use by Lemaire and others of this dressing was the pioneer work of I. P. Semmelweiss in 1847–49 on the ætiology and prophylaxis of puerperal fever—work which was unknown to Lister for many years after his own researches had been published, but which received generous appreciation from him when it was brought to his notice.

What did THE LANCET make of Lister's revolutionary ideas? In our issue of August 24th, 1867, an editorial article, after setting out his principles and describing his practice, credits Lister with a "series of observations which, in point of surgical importance and fine perception of physiological processes, deserves the closest attention of all surgeons and of all physiologists," and states that if his conclusions should be confirmed by further experiment and observation "it will be difficult to over-rate the importance of what we may really call his discovery." This was high praise of such a heretical doctrine and practice, and was not popular with many highly placed surgeons. As the year 1867 progressed, the principles on which Lister worked became more and more clearly defined, and two further contributions to our columns on the Antiseptic Principle in the Practice of Surgery (1867, ii., 353) and Illustrations of the Antiseptic System of Treatment in Surgery (ibid., p. 668) contain many suggestions, founded on basic conceptions of the germ theory of disease, that might well find a place in any modern text-book. The discredit which it was attempted in certain quarters to throw on Lister's theory, when many years later he discarded after a lengthy trial the

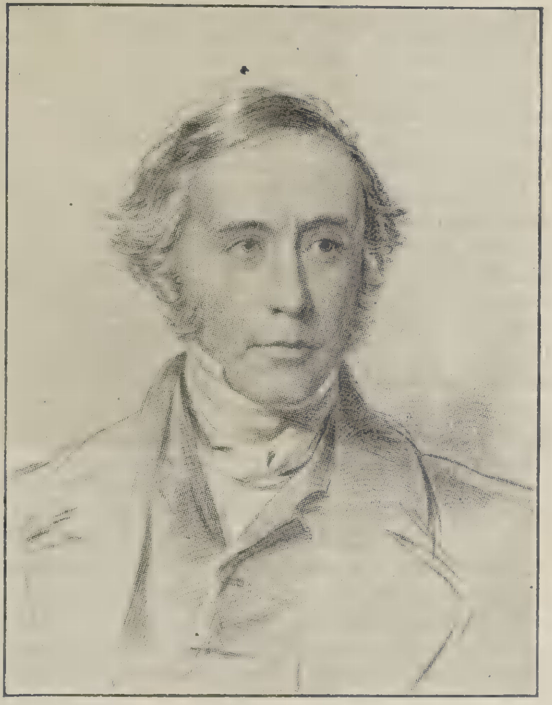

FIG. 32.—JAMES SYME.

carbolic spray, was unfair indeed in the light of his early complete grasp of the essential facts of inflammation, as set out in the second of the papers. He says: "Admitting, then, the truth of the germ theory, and proceeding in accordance with it, we must, when dealing with any case, destroy in the first instance once for all any septic organism which may exist within the part concerned; and after this has been done our efforts must be directed to the prevention of the entrance of others into it. And provided that these indications are really fulfilled, the less the antiseptic agent comes in contact with the living tissues the better, so that unnecessary disturbance from its irritating properties may be avoided."

From the beginning Lister, bearing principles well in mind, was constantly modifying his practice. He soon found, for example, that undiluted carbolic acid in the purification of a recent wound caused superficial sloughing, and after testing and discarding an oily solution 1 in 4, found that a 5 per cent. watery solution was strong enough. In view of the antiseptic-aseptic controversy, it is interesting to observe that Lister recognised the evils of antiseptics in damaging the tissues, and in 1868 was attempting to meet them with the exclusion of germs by mechanical means, such as rubber, or at least to protect the wound by oiled silk. In the search for suitable dressings he discarded in turn putty made from carbolic oil and chalk, paraffin wax and lac plaster, all designed to hold the carbolic acid and prevent its being washed away by discharge, for those which freely absorbed discharges. The first of his absorbent dressings was carbolised gauze, and later cyanide gauze was favoured. The facts will be found in THE LANCET as they occurred.

Lister's methods did not gain ground in London with rapidity, and we allowed ourselves some editorial sarcasm at the expense of London surgeons who had no success therewith. Mr. P. R. Cresswell reported in THE LANCET of August 29th, 1868, that "the use of carbolic acid in the treatment of wounds has created quite a revolution in the surgical practice at Dowlais Iron Works," where 8500 men were employed. We commented the next week on Mr. Cresswell's excellent results, adding: "And yet Mr. Lister's treatment does not find much favour in London. Are the conditions of suppuration different here from those in Glasgow or Dowlais? or is it that the antiseptic treatment is not tried with that care without which Mr. Lister has always pointed out that it does not succeed?"

As Thomas Wakley had done in the matter of anæsthetics 20 years previously, the son now acted. James Wakley was not long satisfied with impressions, but took steps by inquiries at various London hospitals to ascertain the opinion formed by surgeons on its use. As a result of these inquiries, by Nov. 14th, 1868, he was able to record that Lister's method, "sometimes with modifications at the fancy of the surgeons, has been pretty extensively tried at the London hospitals." It does not surprise us nowadays that at St. George's Mr. Rouse "finds the proportion of one part to forty of water too strong as an application for chronic ulceration of the legs. It appears to inflame the neighbouring skin. He now orders a lotion composed of two drachms of carbolic acid to one pint of lead lotion, which he finds very useful." Surgeons at St. Bartholomew's, Guy's, Middlesex, and King's College Hospitals submitted varying reports in the concluding months of the year 1868, some enthusiastic, others damaging.

Meanwhile, suppuration being so much reduced in his hands, Lister's own attention was being turned to ligature material, for with the control of sepsis and absence of sloughing, the conception of reliable ligatures which would eventually be absorbed and organised began to intrigue him. In 1869 he published in THE LANCET a note on the Ligature of Arteries on the Antiseptic Principle, wherein he described his reasons for experimenting on these lines, the preparation of antiseptic catgut and its advantages as ligature material. We pointed out in an editorial comment (1869, i., 503) that whereas it was the custom to regard the ligature as a foreign body, more or less irritating, exciting suppuration and only fit to be roughly removed by the surgeon, "Prof. Lister's experiments lead us to think of a ligature as capable of being absorbed as dead tissues are absorbed, or encapsuled as a metal bullet might be, or incorporated with the tissue of the artery." We called attention in the same article to the discrepancy between Lister's own results and those of certain others attempting to use his methods. This was a useful comment, as it inspired Mr. E. R. Bickersteth, of Liverpool, among others, to recount in our columns his own good results, and to record the first cases in which the antiseptic catgut suture had been successfully used on the human subject for tying an artery in its continuity. (THE LANCET, 1869, i., 743, 811.) Various reports followed in which the inefficient action of catgut ligatures was mentioned. These caused much controversy. Failure was attributed by the friends of Listerism to imperfect preparation of the catgut supplied, and the reports were useful in that they stimulated Lister to study and improve methods for the sterilising and preparation of catgut.

A reformer of Lister's outstanding honesty could not fail sometimes to offend. The resentment aroused by his not altogether tactful Edinburgh lecture entitled On the Effect of the Antiseptic System of Treatment upon the Salubriety of a Surgical Hospital, which reflected rather seriously on the work of some of his former colleagues at Glasgow, was ventilated in our correspondence columns during 1870. It was impossible to doubt who had the best of the argument. On Jan. 15th, 1870, we pronounced that "Prof. Lister has done good service in publishing his experience of the antiseptic system in the Glasgow wards," and we published during that year a series of important papers illustrating his current work. In January, 1870, Lawson Tait began in our columns the first of a long series of attacks on Listerism, and we returned to the endeavour to ascertain to what extent these methods were being "fairly and crucially tried" in London and Birmingham, the reports received being on the whole favourable.

The modifications of the antiseptic technique introduced by Lister in the early seventies were, however, to test severely the faith of those of his adherents who failed to distinguish between the principles and the current practice of his system, and, moreover, caused much discomfort to his surgical team and possibly some harm to the unconscious patient. We reported the address at the meeting of the British Medical Association in 1871, in which he first described the spray method, whereby operators worked in an atmosphere permeated with carbolic acid. For well over ten years this uncomfortable method was bravely persisted in by Lister, until, indeed, the non-pathogenicity of the bacteria in the air was definitely established. Other innovations of this period were of more permanent value, notably the rubber drainage-tube and the substitution in certain cases of carbolic acid by the milder boracic lotion. The drainage-tube adapted by Lister from that used by Chassaignac in 1859 was illustrated in THE LANCET of March 27th, 1875, and is almost exactly like the tube in use to-day. As to boracic acid, "the new antiseptic" discovered in Sweden, he found it (THE LANCET, 1875, i., 604) in the form of watery solution, "highly efficient and much less irritating than carbolic acid." Already he did not use the spray for every case. For example, he wrote on June 5th, 1875 (p. 788), "I need hardly remark that to operate under the spray when the wound communicates with a septic buccal cavity would be an absurdity. The use of carbolic lotion should also be avoided on account of the irritation which it occasions to the tissues. There is, however, no objection to having the sponges rendered pure by wringing them out in mildly acting boracic lotion."

The acceptance of Lister's doctrines abroad was much more prompt and enthusiastic than in this country. We recorded on June 19th, 1875, that his progress through the university towns of Germany has "assumed the character of a triumphal march." His cause received a setback in London through an unfortunate incident. In the early months of 1877 Lister made a speech in Edinburgh which was not intended for publication, but found its way into the lay press, containing a somewhat tactless depreciation of the methods of London schools of surgery. This gave rise to acrimonious correspondence in THE LANCET and to somewhat severe editorial rebuke. The occasion of the speech was the acknowledgement of a testimonial received from his students, on the rumour that he had been invited to leave Edinburgh for London, and should perhaps have been regarded as privileged. Lister showed no resentment at the editorial attitude, for he continued to send his papers to THE LANCET and, indeed, later in a clinical lecture published in our columns (THE LANCET, 1878, i., 5) confesses that his strictures were founded on misconception of the present methods of the London schools, and expresses his sincere regret that certain expressions used "should have seemed capable of casting the remotest possible slur on the surgeons of the Metropolis." His inaugural address to the students of King's College on the nature of fermentation offered clear experimental evidence of the groundwork on which the antiseptic theories were based. In editorial comment on the address, which is well summarised in our columns, we call attention to the skill with which Lister used diagrams and experiments to illustrate his arguments, unusual in those days, and express our conviction that the scientific world would thank him for his lecture. Later in the year he developed the subject in a "remarkably lucid and well-reasoned address" on Lactic Fermentation and its Bearing on Pathology (THE LANCET, 1877, ii., 9, 21), presented to the Pathological Society of London, where he was received with cordial welcome by a packed meeting of his scientific colleagues. Charles Murchison presided, Burdon Sanderson and Charlton Bastian were most cordial.

Nothing less than a revolution was brought about from this period onwards by the gradual spread of accounts of Lister's successful cases among London surgeons. The attitude of the rapidly diminishing opposition is well shown by an anecdote quoted by Sir Rickman Godlee in his Life of Lister. In October, 1877, Lister performed an "open operation" on a broken patella by wiring the two fragments together, then a novel procedure; and a well-known surgeon said: "When this poor fellow dies someone should proceed against that man for malpraxis."

A clinical lecture on a Case of Excision of the Knee-joint, published in THE LANCET of Jan. 5th, 1878, caused considerable sensation, and another lecture on Antiseptic Surgery, published in our issue of Dec. 20th, marked what may be termed the close of the period during which Lister's basic principles were regarded by responsible people as under any doubt. In a leading article we reviewed the situation and expressed ourselves finally convinced that "Listerism is destined to be the surgery of the future." The battle against prejudice was won. Of the publications of Lister, subsequent to this lecture and until his retirement from active practice, a good proportion were published in our columns, as may be seen in the many bibliographies of his works.

THE DISTINCTION BETWEEN PATHOGENIC AND NON-PATHOGENIC BACTERIA: ASEPSIS.

It remains only to note the alteration in technique—for it was no alteration in principle—which led first to the abandonment of the carbolic spray and later to the gradual replacement of antiseptic by aseptic surgery.

The fundamental change was brought about by the discovery that the bacteria in the air were mainly, if not entirely, non-pathogenic, and that if scrupulous cleanliness were adopted in every instrument, dressing, or finger allowed to touch the wound, incisions into tissues not already infected might be expected to heal by first intention. This ideal was developed by the aseptic school founded by von Bergmann[1] in 1885–86, till it reached the stage well known in modern operating theatres, and there is no sign at present that in civil surgery this procedure is likely to be replaced. In war surgery, however, the antiseptic system still largely prevails. The Carrel-Dakin (The Lancet, 1916, i., 880, and 1916, ii., 800) and the bipp method (The Lancet, 1916, ii.) of antiseptic treatment were but extensions of the Listerian ideal, and, in fact, only one (the hypertonic saline treatment introduced by Almroth Wright, The Lancet, 1915, i., 847) of the many methods of treating war wounds which we had occasion to describe and assess during the war was founded on physiological principles other than those elaborated by Lister. The search for Lister's ideal antiseptic which penetrates the tissues without damaging them, and yet is potent to destroy pathogenic bacteria, is not yet ended.

We have gone very fully into the story of antiseptics because some writers in summarising the magnificent work of Lister have consulted our columns partially and have come to the unjustifiable conclusion that, after having supported Lister enthusiastically at first, we later made his course difficult. It was impossible that the swings back of the pendulum, as they occurred, should not be reflected in our columns, but there was never any attack upon Lister, and many quotations from our columns, made to give colour to the mistaken view, would be found on consultation to be extracted from the reports which had to be published, if true information was to be given, and not from editorial articles.

PUBLIC AFFAIRS AND MEDICAL JOURNALISM.

A HUNDRED years of medical events cannot be told without overlapping or repetition unless regard for dates gives way to the claim for a consecutive story, when big things—such things as make epochs by their revolutionary bearing—are in question. In writing of anæsthetics and antiseptics the wish to complete a section recording the relations of The Lancet to these big things has brought up to the days in which we live a narrative broken off under the editorship of James Wakley.

Disrespect for Personages.

There was a side to that editorship to which attention should be paid as furnishing an example of the influence of circumstances upon a journal founded to remedy the ills under which general practice lay and to raise the doctors of the people to the place which their responsibilities should give them. From the beginning this programme had been carried out with fearlessness and fierceness, with the result that much tyranny and back-sliding in high places had disappeared. It was no longer their official lapses, as presidents or professors, which offered to the leaders of medicine opportunities day by day for demanding apologies or for starting libel actions; instead, strictures were meted out to them for their behaviour in public affairs. The ethical rather than the official demeanour was made the subject of investigation, and James Wakley's aspirations for peace were thwarted by the bitter comments which appeared in his columns when social happenings brought the manners of distinguished persons under the criticism of certain of his editorial writers. It will be sufficient to give two or three examples in illustration.

Shortly after the arrival of Napoleon III. in England a consultation took place between Baron Corvisart, his medical attendant, and Sir Henry Thompson, when the condition of vesical calculus was diagnosed and the question of operative interference discussed. But the symptoms abated, and it was not until Jan. 2nd, 1873, a year and nine months later, that Sir Henry Thompson decided to operate with the general medical and surgical support of Sir William Gull and Sir James Paget. Chloroform was administered by Clover himself and lithotrity was performed. Three days later there were indications that further operation was necessary, but before this could be performed the Emperor died. The post-mortem examination revealed a condition which it was suggested in The Lancet could have been better met by lithotomy, while excerpts were published from the back files of the *Union Médicale* showing that at least three years before the disastrous Franco-German War the Emperor's medical advisers had been perfectly aware of his ominous state. These quotations led to disrespectful comment on the wording of the post-mortem report, inasmuch as the very first sentence contained a suggestion that the conditions found at the autopsy were unsuspected, and could not have been ascertained in the course of ordinary diagnosis. Now Sir William Gull dissented from the finding of the other signatories, and his conduct in so doing was considered by The Lancet to have been a pretence to a superior wisdom, which had only been obtained after the tragedy, and the professional attitude adopted was bluntly condemned.

Later the same physician came in for severe criticism because of certain contradictory statements which he had made in the Bravo case, the stages of which were reported in The Lancet. That case was, and for experts in criminology remains, of extraordinary importance, and, during the whole of the protracted inquest with which the proceedings terminated, the daily journals gave prominence to the matter, and made of it a story of standing interest. A quarrel arose between Sir William Gull and Sir George Johnson with regard to the way in which Gull gave his evidence; the allegation of Johnson was that Gull, having been called into consultation because poisoning was suspected, and having been definitely told by Johnson and his colleagues why he was being consulted, suggested in his evidence that the suspicion of poisoning was due to his own sagacity. The Royal College of Physicians of London, to whom the matter was referred, appears to have taken in essentials much the same view as THE LANCET, although the College opinion was expressed in more courteous terms, and the circumstances formed the text of a great deal of writing. Sir William Gull was roundly told that he ought to give an explanation, but looking at the circumstances at this distance of time we cannot see that any obligation to do so was laid upon him.

---

[1] Von Bergmann celebrated the twenty-fifth anniversary of his career as a surgeon in 1885 when he was director of the Kœnigliche Chirurische Universität Klinik in Berlin. In congratulating him we noted the fact that he was engaged on a series of investigations "which are principally a continuation of Lister's inquiries into antiseptics" (The Lancet, Dec. 5th, 1885), and in the course of the next few years were able to chronicle his invention of steam sterilisation and the world-wide spread of his doctrine and practice of asepsis.

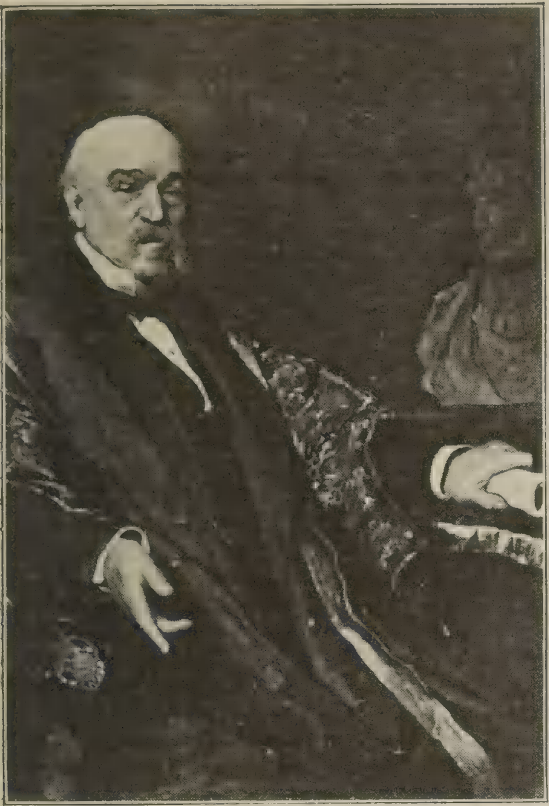

FIG. 33.—SIR WILLIAM JENNER.

The frank way in which the professional conduct of the most successful and perhaps the leading consultant of the world was commented upon in THE LANCET was followed in dealing with the circumstances of Lord Beaconsfield's deathbed, where other eminent physicians were in attendance. It is more than probable that the unfortunate position which medical affairs assumed during the great statesman's last illness, as fully set out in THE LANCET, cost Sir Richard Quain the Presidency of the Royal College of Physicians of London. Both Sir William Jenner (Fig. 33) and Sir Richard Quain were strong candidates for the position, but Quain was generally considered to have the better chance when he decided to take a line different from that adopted by Sir William Jenner in meeting at the bedside a well-known and highly respected physician who included the tenets of homœopathy in his medical creed. Beaconsfield wished to see Sir William Jenner, who had moreover received the Queen's special command to visit him. Quain met Dr. Kidd in consultation, but Jenner declined to do so. There was nothing personal in his action —he took up the line that no grounds existed for consultation between the ordinary physician and the professor of a particularist school. At the election for the Presidency the vote of the Fellows gave Sir William Jenner twelve times the number of votes accredited to Sir Richard Quain (Fig. 34), and for some time the relations between Quain and THE LANCET were strained.

Yet one more instance may be quoted of outspoken writing which had more than a passing effect. A junior surgeon, later a member of the staff of THE LANCET, in the theatre of a London hospital performed an operation in which it was surmised by some that a vessel, not ordinarily in danger, was injured. The surmise was not verified and, most unfortunately, the patient was buried without a post-mortem examination, but one of the senior surgeons to the hospital, who appears not to have been present at the operation, denounced his colleague to the lay authorities of the hospital as incompetent, and, according to THE LANCET, the junior surgeon had received similar treatment on a previous occasion. A furious quarrel broke out, which the staff of the hospital urged should be confined to their own walls; they considered that an interchange of apologies, the senior signing "a mild expression of regret that he did not intimate to the junior his intention to libel him on the condition that the junior should express regret that anything should have seemed to call for inquiry into his surgical conduct" would meet the case. After this summary THE LANCET said that the senior man "had sinned against the very first principles of professional ethics and of ordinary morality." But, alas, the writer of the article impugning the senior's conduct was found himself to have personal reasons

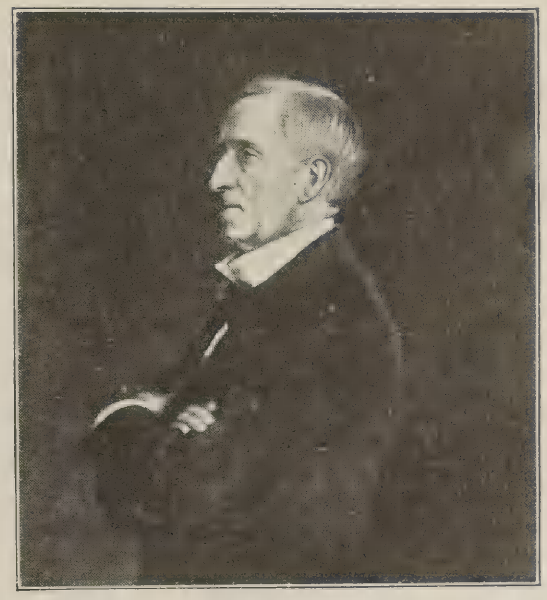

FIG. 34.—SIR RICHARD QUAIN.

for disliking him, and the attitude towards him and towards the staff of the hospital adopted by THE LANCET were so resented by other hospital staffs that, 50 years after the founding of the paper, and at least 30 years after any open quarrelling between the staffs of hospitals and THE LANCET, the paper found itself back again in much the situation in which Wakley was placed at the start of his career. Reports from the London hospitals were not sent to THE LANCET ; those who were supposed to be attempting to obtain information, even of the most strictly scientific sort, for publication in THE LANCET, were warned not to do so ; and some of the interesting publications which appeared in the paper had for a brief period no names attached to them. The action for libel brought against THE LANCET was settled out of court, a considerable sum of money being thus expended, while THE LANCET had to dispense with the services of its most powerful leader-writer.

THE STAUNTON CASE.

A certain number of notorious crimes are chronicled in THE LANCET with great fullness, especially where the medical evidence, as in poisoning cases, has served to determine the issue. Many of these cases have of recent years been made the subject of monographs, and to one such we may call attention because the action of the paper has been much criticised. A review of what actually did happen shows that we were on the side of justice.

In 1877 occurred the celebrated Penge atrocity, when Louis and Patrick Staunton, Elizabeth the wife of Patrick, and Alice Rhodes, Elizabeth's sister, were convicted at the Old Bailey of the murder of Harriet, the wife of Louis. They were sentenced to death by Mr. Justice Hawkins at what appears to have been the first murder trial over which he presided. The capital sentences, however, were not carried out, a result largely due to our efforts made with a remarkable consensus of opinion behind them expressed by a large body of medical men. The squalid story of the Staunton case has been admirably compiled by Mr. J. B. Atlay, in the well-known series of "Notable English Trials" and the details need not be dwelt upon ; but it is worth mentioning, for those who love a sensational story, that the detection of the crime was led up to by a coincidence so remarkable that even a hardened manufacturer of detective fiction might have hesitated to introduce it into his book. Harriet Staunton, the victim, had disappeared from her family ken, when her brother-in-law entered by chance a small shop where he overheard a man, whom he did not know, asking where he ought to register a death of a lady from Cudham. Cudham was the last place from which anything had been heard of Harriet Staunton, and her brother-in-law, having his reasons, followed up the clue and communicated with the doctor. As a result an inquest was held and the arrest, trial, and conviction of the four criminals followed.

Immediately the gist of the long and detailed medical evidence became clear, it was perceived by us that a miscarriage of justice had taken place, owing to the fact that Mr. Justice Hawkins had omitted in his summing-up to give any effect to the medical testimony for the defence, though it had been presented by such unexceptionable witnesses from the clinical and pathological point of view as J. S. Bristowe and J. F. Payne. It would have been impossible to have obtained medical witnesses whose qualities more absolutely demanded that their words should be treated with respect, for they were learned, exact, and experienced men ; a verdict obtained in flat contradiction to their views was almost certain to be one contrary to justice. The point at issue was whether Harriet Staunton had been starved to death or had died of tuberculosis. The proof of criminal neglect of the unfortunate woman was overwhelming, but the judge left the case to the jury as "murder by starvation," while the fundamental proposition—namely, that the deceased had died of starvation—was not only unproved, but was entirely unsupported by the medical evidence. Even the inferences drawn by the medical witnesses for the prosecution were admittedly not warranted by the post-mortem appearances as described by themselves, and THE LANCET took up the ground that it must be impossible to prove murder by starvation without first showing that death had occurred from starvation, and the attempt to affirm that proposition had failed. We considered the issue raised so serious that we asked the medical profession to mark its sense of the emergency by a combined expression of opinion, while making it clear that our view of the situation which we wanted them to endorse, was not suggested by sympathy with the prisoners or a low estimate of their crime. We desired in the interests of justice to place on record a strong belief that the indications offered by a dead body, imperfectly examined, had been misinterpreted, an inference being drawn which the facts did not warrant, but which, on the contrary, they controverted. We invited medical signatures of endorsement. In the same issue of THE LANCET we published a statement by Prof. W. S. Greenfield on the medical evidence of the Staunton case. Greenfield, a member of the staff, was at the time lecturer on pathology to St. Thomas's Hospital, but had already shown the qualities of observation and research, both there and at the Brown Institute, which later gained him so eminent a position in Edinburgh. His submission that starvation alone could not have caused the death of Harriet Staunton was convincing. Some 700 physicians and surgeons, headed by Sir William Jenner, signed a memorial for a reprieve, when Alice Rhodes received a free pardon, and the three Stauntons were sentenced to penal servitude for life.

Bristowe, whose evidence was brushed aside by the judge, was the author of the "Theory and Practice of Medicine," as popular a manual in medicine as Erichsen's book was in surgery. He was one of the best clinical teachers whom the London schools have ever known, and a frequent contributor to THE LANCET. His closest connexion with us, however, was in the early days of his career, when he was in charge of sanitary investigations for the Public Health Department of the Privy

Council before the absorption of that department in the Local Government Board. In 1863 he reported, with Timothy Holmes, on the sanitary condition of the English hospitals. The reports themselves are buried in blue books, but some of their valuable lessons will be found in a statement in our columns from Holmes, and both he and Bristowe for many years kept us thoroughly well informed on institutional matters. In fact, their experiences supplied much of the information which brought home to the second Thomas Wakley the needs of the metropolitan hospitals and stimulated him to his actions in behalf of the Metropolitan Hospital Sunday Fund, now to be described.

We come to a pleasant side of James Wakley's reign when we turn to his constructive policy in the matter of hospital finance, his generosity to Epsom College, and his crusade against impurity in food and drugs. In the last instance what he did was a sequel to work begun in his father's time, and in all three directions he left behind him definite tasks for his successors.

METROPOLITAN HOSPITAL SUNDAY FUND.

The origin of the Metropolitan Hospital Sunday Fund has been the subject of considerable controversy, though of a more friendly nature than usually attends differences of opinion upon questions of priority. In a sense James Wakley was the originator of the Fund which was to furnish a pattern upon which later the splendid organisation of the Prince of Wales's Hospital Fund for London arose. And it is significant that the latter foundation has in no way interfered with the utility of the older movement, with its power of doing good or with the influence of its special appeal.

Before there was any Hospital Sunday Fund in the metropolis a plan for benefiting hospitals in the identical way had undoubtedly been started in Birmingham. Mr. T. B. Wright, editor and proprietor of the *Midland Counties Herald*, broached the subject to Canon J. C. Miller, a well-known Birmingham clergyman, who later became rector of Greenwich. Mr. Wright's suggestion was that the collections taken at every place of worship in Birmingham on a certain Sunday should be devoted to the needs of the medical charities of the city. In 1869 James Wakley determined to undertake the task of making such a method of alms-giving national, and in the year 1872 he succeeded in arousing sufficient interest in the metropolis to launch his scheme successfully. The movement did not spread from London in accordance with the design, though local efforts were noted for a time, especially in the north of England. But from the beginning large subscriptions were received from the provinces to the Metropolitan Fund in recognition of the facts that the hospitals of the metropolis received within their walls patients from all over the Kingdom and that the medical staffs attached to those institutions did work which was in no way confined to the capital.

The part played by Henry Burdett was recognised to the full by James Wakley, as it was Burdett to whom he went when he decided to establish a Metropolitan Fund. When the credit of the establishment of the Fund became a subject of controversy, an historical sketch of the movement, together with the articles which appeared in THE LANCET in its support during the years 1869–72, was written by Burdett and published as a pamphlet. From that pamphlet the following passages may be quoted as both describing the origin of the movement and settling all controversy. Sir Henry Burdett wrote :—

> It was Mr. Wright, the editor and proprietor of the *Midland Counties Herald*, who aroused the late Canon Miller and the people of Birmingham to the fact that collections made simultaneously in all places of worship throughout that town each year in support of hospitals would produce a sum so large as to be remarkable, and results so beneficial to the whole community as to be calculated to ensure for ever to the originators of such a movement the gratitude of many people. Similarly to Dr. James Wakley, the Editor of THE LANCET, chiefly belongs the honour of transplanting the Hospital Sunday movement from Birmingham to Manchester, Liverpool, Dublin, Carlisle, Chester, Birkenhead and many other towns. In the year 1869, when Dr. James Wakley determined to devote himself to the congenial task of making the Hospital Sunday movement national and, if possible, universal by causing it to become popular through the length and breadth of the land, Hospital Sunday was an institution practically confined to Birmingham, where it had been in successful working for ten years.

James Wakley commenced by appealing to the Church itself suggesting that the archbishops and bishops should take counsel together upon this matter and use their utmost endeavours in their several dioceses to establish a Hospital Sunday as one of the permanent institutions of the Kingdom. He asserted that if the Church of England would take the lead, it would be followed with alacrity by the Dissenting community, who are always ready to prove by their action that upon the common ground of Christian charity they are willing to meet their brethren of the Establishment in friendly and emulous coöperation. The moral effect of a nation unifying for public recognition of the claims which the sickness and suffering of those who are not able to pay for medical treatment and care would have upon those whose means are sufficient for their own and others needs would, James Wakley asserted, be huge. The practical result would be that in enabling medical charities to maintain and extend the sphere of their operation by the additional support they would derive from the Hospital Sunday collections, numbers of persons would be prevented from becoming permanently chargeable upon the poor-rates, and thus the tide of advancing pauperism would have at least one of its sources dried up.

> "Dr. Wakley," says Burdett, "found the task he had set himself to perform no easy one ; that the very people whom he wished to benefit were largely apathetic and slow to adopt his views ; and although several of the large provincial towns gradually followed the example set by Birmingham, it was not until after three years' advocacy and a special appeal to Sir Sydney Waterlow on his assuming the office of Lord Mayor in 1872 that any practical impression was made upon the metropolitan hospital authorities or the inhabitants of London. As was remarked in THE LANCET at the time, if these gentlemen were

blind to the advantages which a Metropolitan Hospital Sunday Fund offered, or were too apathetic to take any measures for securing them, it was not reasonable to suppose that anybody else would put the bread into their mouths."

Wakley combated the many objections urged against the new project, and the first meeting of supporters was held in The Lancet offices, with Canon Miller in the chair. On Nov. 30th, 1872, Wakley stated that Sir Sydney Waterlow, the then Lord Mayor, was entirely in favour of a Metropolitan Hospital Sunday Fund and had promised to give it his warmest support. On the same day he reprinted a series of articles which had appeared in The Lancet from 1869 to 1872 in support of the Hospital Sunday movement, which were written by Burdett and Brudenell Carter. The circulation of this pamphlet, followed by the meetings of a representative committee which was specially formed, resulted in a conference of gentlemen, including clergymen of the Church of England, the Archbishop of Westminster, and the Roman Catholic clergy, Dissenting ministers of almost every denomination, members of the Jewish persuasion, the Archimandrite of the Greek Church in London, together with many laymen of all churches at the Mansion House on Jan. 16th, 1873, under the presidency of the Lord Mayor (Sir Sydney Waterlow) for the purpose of forwarding the movement for establishing a Hospital Sunday over the whole metropolis similar to that which had been adopted in Birmingham, Manchester, Liverpool, and other large towns.

From this meeting onwards Sir Sydney Waterlow took charge of the Metropolitan Hospital Sunday Fund, of which he became the active spirit. It is clear, then, that divided honour is due to T. S. Wright, Canon Miller, Sir Sydney Waterlow, and James Wakley as the founders of the Metropolitan Hospital Sunday Fund in Birmingham and London respectively. Wright and James Wakley, by the weight of their influence and official positions, turned the scheme into fact, and James Wakley gave to the Fund £1000 on two separate occasions, while he also left the same sum to the charity in his will.

The following is Mr. Brudenell Carter's story of the actual foundation of the Fund :—

> "When I joined The Lancet staff in 1868," he says, "Dr. James Wakley was editor and he was very anxious to obtain the establishment of Hospital Sunday. He caused several articles to be written on the subject by myself and others, and finally asked me whether I could not do something with the *Times*. I went to Delane on the subject and he said that he was not prepared to commit the *Times* to the proposal, although he thought well of it, but that he would publish every extract from The Lancet with regard to it that was sent to him. We took full advantage of this, and The Lancet almost weekly had a paragraph on the subject, all of them appearing also in the *Times*. About the same time I discussed the question with the Duke of Westminster who was treasurer of St. George's and often there, and also with the Bishop of London, Dr. Jackson, whom I had known before his elevation to the Bench. Both were at first opposed to it, the Duke thinking that the annual collection would withdraw subscriptions, the Bishop that different religious bodies would never be got to combine. In due time all difficulties were overcome and a great meeting was held at the Mansion House for the establishment of the Fund. I went in before the chair was taken, while people were still standing about, and caught the Duke's eye, who beckoned to me. I went up to him and he pointed to the Bishop, who stood near him, and said, 'Here Carter, come and sit between two converts.' I was on the first council of the Fund."

Mr. Brudenell Carter's letter, written 50 years after the event, was a purely personal account of his own share in the movement, and this it will be remembered was very large, for he was one of the principal authors of the numerous articles which appeared in The Lancet advocating the scheme, while he also, from his position as medical adviser to the *Times*, kept the columns of that paper open with steady persistency to the advocacy of the Fund.

The omission of Burdett's name was unfair, and was due to a belated recollection of the strained situation which arose between James Wakley and Burdett when Wakley refused to publish in The Lancet a weekly supplement dealing with hospital and institutional matters, to be edited solely by Burdett. Wakley did not consider it possible then to delegate his editorial authority, and Burdett thought that it was designed to use him for the aggrandisement of The Lancet. The result of their difference was the founding of the *Hospital*, which Carter resented, as he had advocated the hospital supplement in The Lancet.

The first collection was made on June 15th, 1873, when there were 1072 contributing congregations, and the total receipts in London amounted to £27,000. The totals increased with almost steady persistence till 1895, when they reached £60,361, the contributing congregations numbering 1807. In the next three years there was a fall in the total, but after that it steadily mounted again, till in 1922, the last year for which the figures are available, the total stood at £100,889 with 2162 congregational contributors.

Epsom College.

Epsom College was founded by Dr. John Propert, and the movement received from the beginning the warmest support of James Wakley. John Propert's object in founding the school was to assist medical men by educating their sons well and economically. He strove to obtain support to constitute a Foundation of 50 boys, the foundationers to be the children of medical men where circumstances had prevented the children from enjoying the usual opportunities of the sons of professional men. The terms of the Foundation almost implied that the father should be either dead or incapacitated from medical practice. Queen Victoria granted her patronage to the College at the very outset, so that the Medical Foundation was assisted from the beginning by the appellation "Royal." The subscriptions came in fairly promptly, and within two years of the initiation of the movement a part of the institution was declared open, but considerable as the sum at the disposal of the governing body soon became, it was far from adequate to meet the intended expenses, and the columns of The Lancet contained time after time pleas to medical men to add their names to the list of subscribers, some of them written by William Carr and others by Glover. Carr collected over £2000 from old University College men. The proprietors of THE LANCET acted up to their words and sent £1000, and from that day forwards the interests of the College have always been forwarded by the paper. In particular were all developments tending to make of Epsom College a great and general public school fostered and approved, it being seen that the children of one class going to a purely class school would themselves lose half the benefit of English public school education. Further, and taking the development of Eton and Winchester in proof, it was certain that where the best facilities are provided in behalf of a Foundation parents whose children cannot enjoy the pecuniary advantages of the Foundation will send them with great readiness to share in the educational opportunities. It is well known now that Epsom College, though its initial reason was its Royal Medical Foundation, ranks on general grounds with the large public schools of England.

THE MEDICAL ACT OF 1886.

In 1886, the year of James Wakley's death, the Medical Act of that year (49, 50 Vict. Cap. 48) was passed to amend the Medical Act of 1858. During the 28 years under which medical registration and education had been carried on and medical discipline organised under this Act, some weak spots had revealed themselves in its working, while the development of the medical profession had been such that situations had arisen which had not been contemplated by the original reformers. Throughout the whole period we find THE LANCET putting forward arguments which had been employed when the first medical reform measure became law, and to a certain extent the amending Act was in consonance with the views expressed. The state of the medical curriculum had become inchoate from the fact that, leaving the universities apart, the several corporations were able, each without reference to the other, to grant a complete qualification to practise without having held an adequate examination in the three principal departments of medicine—namely, medicine, surgery, and midwifery. The perfunctory nature of the examination, now in one subject and now in another, was constantly referred to in THE LANCET, with the implication that under the original scheme, put out by THE LANCET, such troubles would not have occurred. When the Medical Bill of 1886 became law it had a mixed reception. The way in which revealed defaults were to be met did not seem to many of the more advanced thinkers to be satisfactory, while certain aspirations towards the institution of a universal diploma were brought definitely to an end. The new legislation provided that admission to registration should follow a qualifying examination in medicine, surgery, and midwifery, to be provided (1) in any university where the necessary educational facilities were forthcoming; (2) by a combination of a university with a medical corporation so as to provide these facilities; or (3) by any combination of two or more corporations in the same part of the United Kingdom who by agreeing to hold a joint examination would cover the whole curriculum. Thus were produced the conjoint boards under which the most valuable part of the education of the country is now carried on, and by so doing it simplified and codified the previous system of medical education, and suppressed a great deal of isolated and inadequate examination.

The main fault found with the Act was that the number of examinations and of separate examining bodies still remained far too great, and to THE LANCET it was a disappointment that a well-organised movement for the institution of a one-portal system, which started in 1869, had made no converts in the legislature. The advantages of such a reform were pertinaciously pointed out by the paper. Certain corporations were able to give to their diplomats a complete and legal right to practise medicine in its three branches of medicine, surgery, and midwifery without there being any guarantee that the students were adequately examined in all three subjects. From this fact arose the feeling that a surgical corporation would be well advised to coöperate for examination purposes with a medical corporation and make thus a joint board whose tests should be fully inclusive of the three main headings of medical education. Having got thus far in a scheme of amendment it was logical to include in the movement the universities, and thereby prevent any down-grade competition between the various examining bodies. In this way the idea of one examination board for England, or of three examination boards, one for each division of the United Kingdom, arose, and having arisen took such a powerful hold on the reason of the leaders of medical education that in the late "seventies" a one-portal system as nearly as possible was established. By 1875 one corporation after another and one licensing body after another had approved of a one-portal system and had expressed their desire to coöperate and establish a common examination board. But one by one they raised later some objection to the conjunction, or found at the eleventh hour that by the provisions of their charters they were unable to enter into the combination which they desired. Yet these recurrent impediments were got over, and eventually all legal obstacles were removed. It seemed to everyone that the chief difficulties to a speedy coöperation of the various bodies had disappeared, and that nothing remained, except the settlement of preliminary details, to oppose the formal combination in England of the Royal College of Physicians of London, the Royal College of Surgeons of England, the Society of Apothecaries of London, and such universities as at that time were represented upon the General Medical Council; and this expression of opinion was published in THE LANCET, where every phase of the movement was carefully followed, and where also the temptation to prophesy was fortunately resisted. The Scotch and Irish bodies were not so ready as the English bodies, but the probability is that if the English bodies had been able to come to a working agreement for the establishment of a one-portal scheme for England they would have been followed in the sister divisions of the country. But at the last moment the plans of amalgamation came to nought. One body, and one body only, unexpectedly stood out upon one point, and one point only, and before this dissenting body could be brought again into line the unity of opinion had ceased to exist.

To those who had had the idea of a one-portal system at heart the Act of 1886 was a disappointment, but to-day we can see reasons for other feelings. Undoubtedly the establishment of a one-portal system would have been a great stride towards the erection of a State medical service, and against that THE LANCET was and is firmly opposed.

THE LANCET IN THE 'EIGHTIES.

CLINICAL WORK.

THE output of every paper, which has a reason for its existence and would try to justify it, will be divided roughly into work recorded and work done; and the confining of this *apologia* largely to the latter category is not due to egoism but to necessity. No reasonable summary can be made of the work recorded in our columns, as done by those who have had the conduct and progress of medicine in their hands for a century. It would be useless to detail the important scientific communications which we have published throughout such a period, and even to make any wide selection from them on the score of their permanent value would be impossible over the whole range of medicine. In the chronicle of the earlier years something of the sort has been attempted, for in those days clinical medicine was far simpler, more traditional and empirical, and infinitely less divided and subdivided into special ranges of energy. We have, therefore, recalled as a matter of historical interest the names and writings of those fathers of medicine who published in THE LANCET, almost from its appearance, what proved to be the foundation of later and more systematised knowledge. We have also tried to show briefly how from the middle of last century until to-day our pages have reflected medical accomplishment and medical opinion, as the first was acquired and as the second was established, by telling in some detail how we dealt with two grand factors in medical science, the use of anæsthetics, and the discovery of antisepsis and asepsis.

The rise in the standard of medical education, following the provision of opportunities for students, led to the developments in medical science for which the latter half of the nineteenth century has earned perpetual fame. These in their turn reacted on the course of training, in case of both teacher and taught, causing the range of discovery and invention to extend indefinitely. We have endeavoured to keep pace.

James Wakley died in 1886, and during his tenure of the editorial chair the whole of medicine, as we understand it to-day, came into being. His contributors told of the rise of physiology and its gradual influence on pathology, of the beginnings of biochemistry, and of the influence of Darwin's work on medical aims. They wrote of a surgical technique and pathology, slowly or rapidly being revolutionised; they recorded fundamental advances in neurology, electrology, and obstetrics, and the discovery of the bacilli of tubercle, cholera, and tetanus, and the presence of the hæmatozoon in the blood of malarious subjects. In the year following James Wakley's death came the discovery of the bacillus of Malta fever, and then in rapid sequence we have the arrival of inoculation for rabies, the antitoxin treatment of diphtheria, and the discovery of the bacillus of plague.

The most marked feature in the clinical side of THE LANCET at the latter end of the nineteenth century is the amount of space devoted to the growing science of tropical medicine. In every volume, and often in many consecutive issues, the stories of plague, malaria, sleeping sickness, yellow fever, and kala-azar are related. We were not always the first to announce the discoveries, though that has been our privilege, and full reports of proceedings at international congresses kept us, as well as our readers, true to the bearings. We were certainly advised from the conservative point of view in connexion with malaria, as apparently the fact that the rôle of the mosquito had been definitely ascertained was not acknowledged as telling the whole story until 1900, but in the matter of sleeping sickness, cholera, and kala-azar communications and reports were well up to date and the conclusions quickly arrived at. On the discovery of the Rontgen rays the immediate developments in diagnosis and treatment which would follow thereon were foretold. It may not have been a very remarkable prophesy, but from the purely journalistic point of view it has been interesting to find that the first pathological radiograms to be published were in our pages.

In 1903 came the demonstration that sleeping sickness is transmitted by the tsetse-fly, and two years later the parasite of syphilis was discovered, leading up to the rational treatment of that human scourge.

In returning here to the story of ourselves, enough has been said to show that at James Wakley's death the scientific and clinical departments of the paper were congested with the mass of work, developing in all directions, of which a weekly review had to be made.

THE CO-EDITORSHIP.

The embarrassment in telling a consecutive story has again become apparent. In the description of the scientific discoveries of the 'eighties a jump ahead has been made of the domestic chronicle to which we now return.

The situation which arose at the death of the Founder of THE LANCET was more or less repeated upon the death in 1886 of his successor and youngest son, for just as James Wakley had assisted his father for some three or four years before taking up the editorship, so Thomas Henry Wakley, the Founder's eldest son, and Thomas Wakley, junior, the Founder's grandson, had been engaged in the editorial duties before the chair was vacant. So that on the death of James Wakley there stepped into his place as joint editors his elder brother, who had been, as manager of THE LANCET, associated with all the business side of the journal for 20 years, and his nephew Thomas Wakley, jun., who had learned the editorial routine from his uncle, and from the very competent staff which James Wakley had got around him. The majority of these continued their coöperation, and there was no break whatever in the policy of the paper or in the manner in which that policy was carried out. The most marked feature of the period was the steady increase in the size of the paper, indicating the directions in which evolution had taken place in the practical side of journalism—medical as well as lay. Speaking generally, for the first 30 years of the life of THE LANCET it was difficult to obtain medical information because publicity in its columns was resented and feared by a great many institutions and individuals, and this feeling was reflected in the reluctance of some authors to communicate their work to the paper. During this period, therefore, all the information in THE LANCET had to be worked for, and the fact that most of the important proceedings at institutions and societies were reported, and most of the scientific communications which really made medical history were published, form a proof of great determination. During the next 30 or 40 years the position gradually, and at last rapidly, altered. The violence and extravagance of the early days were seen to have been honest if sometimes extremely disagreeable methods for securing reforms, and as the evils complained of were proved to exist the remedies suggested were more or less adopted, and in proportion as they materialised the abuses disappeared. As hospital organisation improved and as efficiency was made the one great test for admission to the staffs, the necessity, as the first writers in THE LANCET conceived it, of abusing the medical charities faded away. When the system of education improved and the reforming Acts of Parliament got on to the Statute book the patent reasons for violent criticisms of the Corporations disappeared also, but it must be admitted that while systems and institutions were treated with the increased respect which they deserved individuals were still freely handled. Sufficient examples of these have been given, and it is well to record here the somewhat surprising fact that the furious quarrels to which allusion has been made left behind them no abiding rancour.

THOMAS HENRY WAKLEY.

Thomas Henry Wakley, who succeeded to the editorial chair, was even more retiring from professional and social life than his brother James; the two brothers, indeed, showed great similarity of personal characteristics and temperament, although their preliminary educations differed widely. And the life work of each, as far as it was connected with THE LANCET, was very similar, the parallel having originated in the fact that each regarded his position as an heritage from the father, who founded the paper, and considered the first programme to be a constitution which could not be departed from without grave reason.

Thomas Henry Wakley was born almost contemporaneously with the paper, and during his boyhood the sensational proceedings of THE LANCET were attracting the notice of the legal and medical professions. He was sent up to Wadham, but while still an undergraduate University College, London, was founded with a famous medical faculty in attachment, and as he intended to practise medicine he transferred himself to London without taking his degree at Oxford. In those days the medical teachers, or professors, at University College were an extremely distinguished band, numbering among them Samuel Cooper of the Surgical Dictionary; Liston, reputed the finest operator in London; Richard Quain, the author of "The Anatomy of the Arteries"; Anthony Todd Thompson, author of "The Dispensary"; Robert Carswell, the famous pathologist; Robert Grant, the comparative anatomist; and Sharpey, the leading physiologist of the day. It will be remembered that the lectures of many of these savants formed the conspicuous characteristics of the early numbers of the Journal. An industrious student, therefore, had extraordinary opportunities at such a school, and young Wakley became known to more than one of his teachers as a promising pupil. He was also admirably coached, for his father secured Erasmus Wilson, at that time lecturer on anatomy at the Middlesex Hospital, to read with his son. Wilson and his pupil got on well together, and Wakley acted as demonstrator at his coach's private classes with great benefit to himself.

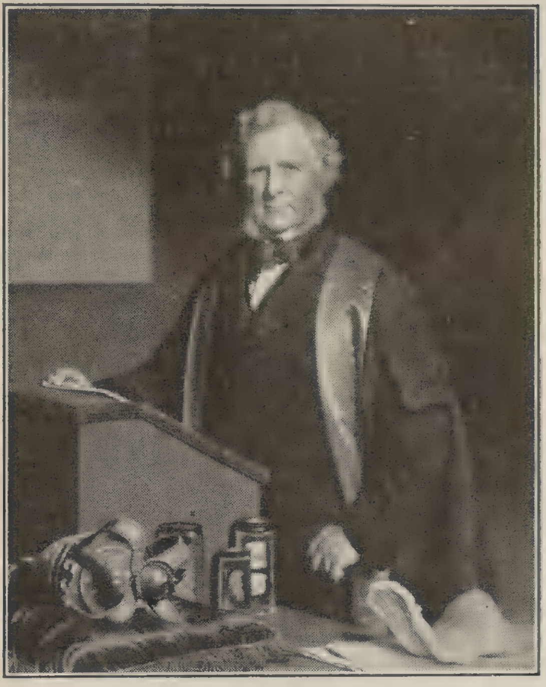

FIG. 35.—SIR ERASMUS WILSON.

(William James) Erasmus Wilson (Fig. 35) was the pupil of Abernethy and of Lawrence, and after demonstrating in anatomy under Jones Quain and Richard Quain, started a private school of anatomy.

at which time he became T. H. Wakley's tutor. The scholastic venture was not successful, and he applied to the Middlesex School for employment, and at the same time was appointed assistant editor of THE LANCET. He himself attributed his determination to become a dermatologist to the senior Wakley's advice, and it is an often told story that Wakley bade him link his name so closely with skins that when he entered a room the company would scratch themselves. (The story is told of other dermatologists possibly with equal correctness.) His enormous success need not be dwelt upon; his benefactions to the Royal College of Surgeons of England, over which he presided in 1881, amounted to over £200,000, in addition to which he gave large sums of money to Epsom College and the Sea-Bathing Infirmary at Margate, and defrayed the expense of deporting Cleopatra s Needle to the Thames Embankment. He was an assiduous and scientific worker, who owed his great pecuniary reward to these qualities, and also to a remarkable use of opportunity. His field of medicine was unexplored, so that when he broke ground he enjoyed almost a monopoly, while he made large investments in gas and railway stock at judicious moments. He remained assistant editor definitely for about four years, but during much of his life his association with the paper was very close. The post of assistant editor did not then entail the interviewing, letter-writing and office routine which later were called for, and daily attendance was not called for.

In the year 1845 T. H. Wakley took the Membership of the Royal College of Surgeons of England, having previously proceeded to Paris in deference to his father's views that the scheme of medical education enjoyed by the Parisian students was preferable to that of the London medical schools. In Paris he lived with Dr. J. Henry Bennett, a well-known gynæcologist, and was an assiduous attendant at the cliniques of the best operating surgeons in the city. When he was not engaged in medical studies he spent his time and his money in taking music lessons, with the result that when he returned to England he was a trained musician and good French scholar, as well as a surgeon of large experience considering his age. In the year 1848 he was elected assistant surgeon to the Royal Free Hospital, a hospital which had been started as a protest against the system of letters by which subscribers to the medical charities of London were able to dispense patronage upon exclusive principles. This hospital made a great stride forward in 1842, when it was removed to its present site, and the appointment formed an admirable opening for a young surgeon. Wakley entered into the spirit of his duties with enthusiasm. He felt that he had got his chance while he was a junior man, but, although he was by no means blind to the advantage of having his father and THE LANCET at his back, he set out with the intention of making a name for himself in surgery. He took a house in Guilford-street so that he might be near the hospital, and for several years became, more or less on his own initiative, casualty surgeon to the institution. His house was so near to the hospital that it was inevitable that the resident staff should appeal to him in all cases of difficulty, and he was delighted with the opportunities which he thus got for increasing his experience.

He soon found that the value of having a distinguished father, who was also aggressive, had its drawbacks. If there was one point on which that father had been more clear than another it was the mischief done at the metropolitan hospitals by the appointment, through nepotism, of the wrong man. When, therefore, the son of the Editor of THE LANCET, while still quite a young man, and with a record for work behind him which had largely been accomplished in another country, was appointed to the staff of the Royal Free Hospital, all the critics of THE LANCET were prepared to consider that the appointment was an example of the very abuses against which THE LANCET was ever fulminating. The second Thomas Wakley soon became conscious that his hospital practice was attracting an amount of interest not usually manifested in the work of so young a practitioner, and both father and son were ill-advised in the publication of frequent communications in THE LANCET over the son's name. But when the attack came its victim was not found unprepared. He was accused of malpraxis at the hospital, refused to pay blackmail to the parents of the child on whom he had operated, and disregarded a scurrilous and indecent pamphlet purporting to be a record of the case, although this was hawked about the street where he lived. An action was at length brought against him *in formâ pauperis*, and the accusation came at an extremely inconvenient moment, for he was intending to present himself, just about the probable date of the trial, at the final examination for the Fellowship of the Royal College of Surgeons of England, instituted six years before. Some of the examiners had been subpœnaed to appear for the prosecution, but he resolved to present himself, and passed on Dec. 6th, 1849, a date which, by the way, bracketed him at the time of his death as senior Fellow of the College. The trial came on Dec. 10th, and was a triumph for Wakley. The only surgeon called for the plaintiff gave evidence for the defendant, the unanimous and authoritative opinion of whose witnesses could not be questioned. The private malevolence which, together with the hope of blackmail, had instigated the prosecution was fully revealed, and the jury, who had previously manifested a desire to stop the case, found a verdict for Wakley without leaving the box.

The ordeal probably increased his professional status, for shortly afterwards he migrated to Arlington-street, where he gained a considerable practice as a general surgeon and made a special study of orthopædics. He also invented several instruments which had a certain vogue for a time in urethral surgery, and he appears to have been the first observer to see the use to which glycerine might be put owing to its hygroscopic properties. But when in 1862 his father died, while the editorial conduct of THE LANCET passed to James Wakley, Thomas Henry Wakley, as part proprietor of the paper became actively interested in its conduct. For many years, while still in practice, he came

THE OFFICES OF THE LANCET.

daily to THE LANCET offices, finally retiring to become manager, and later Editor, in joint editorship with his son, the third Thomas Wakley.

Many can recollect Thomas Henry Wakley, who died in 1907 at the age of 86. Of unbounded activity, physical and mental, he was never ill and never absent. In all weathers and on all occasions he arrived in the early morning at his desk. For many years he spent the winter months in Brighton, but he never allowed this to interfere with his regular and punctual attendance. So late as 1903, when he was in his eighty-second year, he made the journey from Brighton to London and back daily, giving the lie to the gloomy prognostications of the effect of such transits on elderly persons. During the last decade of his life the editorial management of the journal passed from the hands of the father to the hands of the son, but to the end the senior showed no abatement of interest in the details of the paper. One subject he retained in his own hands entirely. During all the period in which he was associated with the editorship of THE LANCET great prominence was always given to the work of the Hospital Sunday Fund, largely founded by his brother. Thomas Henry Wakley resolved that the interest manifested by his brother should not be allowed to die out. He personally supervised the publication every year of a special supplement issued in the interests of the Fund, and only with great reluctance permitted this feature of the paper to be modified when it became clear that the movement was established permanently in the public mind as one to be supported. His deep sympathy with the material welfare of the medical profession was shown not only by his acts of private generosity but by the institution of a relief fund intended to meet unforeseen and urgent pecuniary exigencies among members of the medical profession. His particular adviser in these matters was Sir Andrew Clark (Fig. 36), who published much of his comparatively few writings in our columns. But the friendship between him and the editor had little or nothing in connexion with them. To Clark he went when he wanted an opinion on medical situations, when the view of a man of the world as well as a professional leader was needed, and a real friendship was always maintained between them.

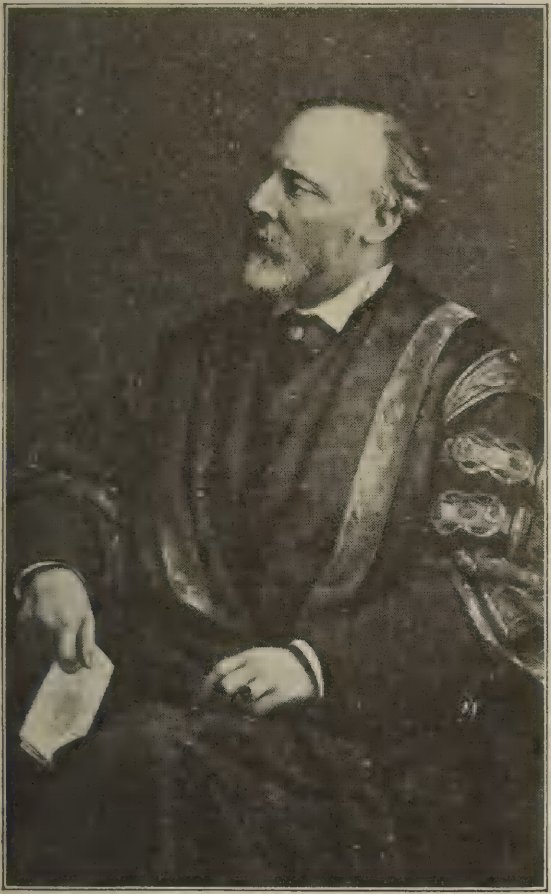

FIG. 36.—SIR ANDREW CLARK.

The proved utility of this scheme of practical generosity was always a source of great satisfaction to its originator, and the Wakleys, father and son, during their editorship, disbursed some £6000 in this way before the situations which it had been designed to meet no longer arose or were better met otherwise. T. H. Wakley was also a warm supporter of Epsom College, his advocacy of this foundation taking the practical form of a donation of £1000, given in the name of the proprietors of THE LANCET. Throughout the whole of the editorship of Thomas Henry Wakley he was loyally assisted by his son, Thomas Wakley, jun., who was already conversant with the mechanical side of newspaper production. And circumstances allowed at this time opportunities for peaceful development.

SOME LOYAL FRIENDS.

James Wakley upon his death-bed left behind him a message to the readers of the paper, which was duly published in THE LANCET. In this message he desired to record "that he had been materially aided in anxious editorial work by Mr. John Tweedy, Dr. J. A. Marston, and Dr. J. G. Glover, with whom he had for many years been very intimate, entertaining great regard and esteem for them, and having great reliance in the soundness and fairness of their judgment, their scientific and literary ability, and the integrity of their character." He was also anxious that tribute should be borne to the work done by Dr. A. H. Hassall, when THE LANCET exposed the adulteration of the food of the people, and "to the long and faithful services of Mr. H. A. Beckett, the present sub-editor of the journal." A few words on the character and work of these valuable friends are fitting.

Henry Arnold Beckett (Fig. 37), sub-editor of THE LANCET at James Wakley's death, was an interesting personality. He had been connected with the paper, first in the printing and later in the editorial departments, from boyhood. He was brought over from the printing department by the original Thomas Wakley, who had been attracted by his gift of memory. THE LANCET was still of moderate size, and Beckett became the editor's private proof-reader. With untiring industry he read the proofs of the whole paper, and what was at first a rule-of-thumb proceeding became in time a highly intellectual performance. For Beckett was determined to understand the gist of what he read, and in the course of his duties became an absolute dictionary of information on professional subjects. Not only did he know the personalities and literary records of hundreds of medical men, but he obtained from them explanations of their words, and sometimes of their actions, which enabled him to follow arguments and disentangle differences of opinion. He had no medical education, but he obtained a wide if theoretical knowledge of medical science in three different ways simultaneously. He supervised the indexing of THE LANCET for years, and his recollection of back numbers was extraordinary: his large and variegated reading was so carefully performed, and with such attention to the author's meaning, that much of the essential teaching was made his own: while the numerous interviews that he had with medical authors concerning the contents of their papers were always turned by Beckett into opportunities for increasing or revising his knowledge. Lister personally explained to Beckett the reasons of many of his procedures, in order to make quite clear to him why he considered some of the objections taken to them mistaken or unfair.

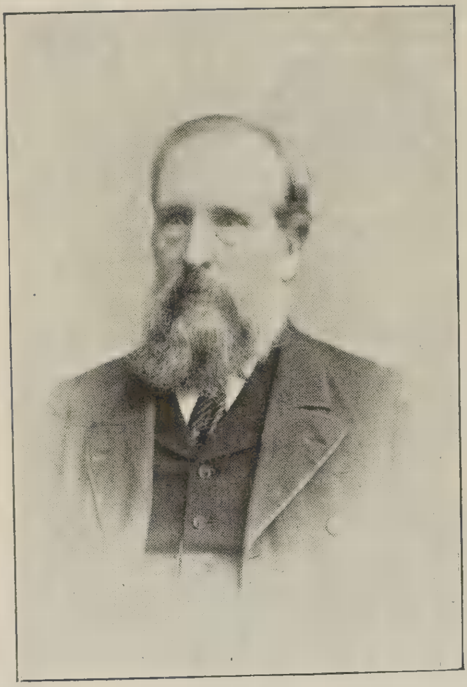

FIG. 37.—H. A. BECKETT.

Sir John Tweedy, Surg.-General Marston, and Dr. Glover remained to support the new Editors, and of these the first is still with us, and it is entirely unnecessary to tell a medical audience what part he has played in medical life or to embarrass him by recording the unanimous view of the high and sterling quality of his scientific and official work. But it must be recorded in a history of THE LANCET that Tweedy had been definitely offered the editorship of the paper with which he had been connected closely since the age of 21, and for which he had done such splendid work as general surgical supervisor, discharging at the end of James Wakley's life all the functions of a joint editor. Acceptance of the offer would have entailed a sacrifice of prospects which, tempted though he was by many of the aspects of journalism, he could not consider. But until his professional commitments made it impossible, he continued to help the paper week by week for many years; indeed, to-day we call upon him, and have done so freely in the compilation of this record.

Surgeon-General Marston was for many years our adviser upon all medico-military subjects, and the numerous editorial articles advocating reforms in the Services, detailing grievances or applauding advances, which appeared throughout a period of great changes, were mainly from his pen. His views were conservative, and he did not always see eye to eye with those whose interests he was most concerned to maintain, but the soldier-doctor never had a warmer friend. He entered the Army Medical Service in 1854, and soon made his mark both as scientific and executive officer. As a surgeon-major he superintended the scheme for a hospital-ship service with the Ashanti expedition (1873–4), and in 1877 was the medical member of the Committee appointed by the Secretary of State for War to draw up the dietary for military prisons. In December of the same year he was appointed secretary to the Principal Medical Officer of the British Forces in India, in which capacity he prepared the schedule of field hospital organisation for the Afghan War. His work proved of great value, and in 1882 he was appointed sanitary officer to the Egyptian expedition and was present at the Battle of Tel-el-Kebir. He was later head of the Statistical and Sanitary Branches at the Army Medical Board and during his official life he kept closely in touch with scientific medicine. His lectures on military hygiene to the medical officers at the Army Medical School at Netley were valuable résumés of the known, as well as sound forecasts of probable developments. In the autumn of 1887 he was sent by the War Office as a British army medical delegate to the Ninth International Medical Congress held at Washington, and in 1888 he went to Egypt as P.M.O. of the British forces serving there, and was responsible for the medical arrangements connected with the contingent sent to Suakim. On his promotion to the rank of surgeon-general, in 1889, he was transferred to Gibraltar, whence he returned to retire from the Service. After his retirement he became President of the Army Sanitary Commission and a member of the Indian Medical Board. Perhaps the most valuable official document for which Surgeon-General Marston was responsible was his report to the War Office upon the Washington Congress mentioned above. In this report he emphasised the importance, especially in field operations, of reducing as much as possible the number and bulk of medical remedies employed, and testified in the early days of compressed drugs to the usefulness of carefully-prepared tablets. His favourite anticipation for the British Empire, however, was an Imperial Defence Service, in which room would be found in different sections of the service for all good qualifications, whether physical or mental. For 30 years, whenever his conditions of service allowed, Surgeon-General Marston was a regular member of our staff, and although in the decade before his death in 1911 he had ceased to give much active help, in matters of which he had expert knowledge, his advice was often sought up to the last week of his life. During his periods of practical journalism he was found by all his colleagues to be a combination of good nature, wide reading, and shrewd criticism. He had a great sense of the dignity of the medical profession, but at the same time was contemptuous of a too narrow professional spirit, and it was this attitude which led to a belief among the most advanced in the demand for a Royal Army Medical Corps that we were not sufficiently warm in putting forward their views. Marston's frankness of diction in the columns of THE LANCET did not always please the professional public, but his simplicity and directness delighted those with whom he came into personal contact.

Dr. James Grey Glover exerted a wide influence over the policy of THE LANCET for a period of 37 years. He graduated at Edinburgh, came under the powerful influence of Christison, Goodsir, Alison, Syme, and Simpson, and arrived in London in 1864 at the age of 32, when he started in general practice in Highbury, living for most of the time at 25, Highbury-place, the house which had once been the home of Joseph Chamberlain. He was a Whig, a nonconformist, and a highly-endowed practitioner, who regarded the profession of medicine as a noble mission. He was well-read in general English literature, especially that of the eighteenth century, which gave to his writing a combination of clearness and classical flavour. He was a deeply religious man, with as strong a desire to remedy social as physical ills. Before leaving Edinburgh he had sent to THE LANCET an article entitled "A Physiological View of the Premier, Lord Palmerston," which had attracted much attention, had been copied into scores of newspapers, and made the subject of verses in *Punch*. On his arrival in London James Wakley invited him to send further communications, and soon found Glover a trustworthy and sagacious colleague. He became James Wakley's lieutenant in all the Metropolitan Hospital Sunday Fund movements, and continued to act in that capacity, but his special work at THE LANCET, under the new Editors, was to take charge of all questions affecting general practice. When in 1886 direct representation of the profession on the General Medical Council was secured, Glover was elected at once and was re-elected time after time for 16 years until his retirement.

The status of the general practitioner had risen enormously under the Acts of 1858 and 1886 and a large number of new questions had arisen, such as the registration of midwives and the use or abuse of unqualified assistants. Discussion of these topics was frequent and free over many years, and their conduct was confided to Glover.

REGISTRATION OF MIDWIVES.

At the close of the century there was a plethora of suggestions for dealing with the question of the unregistered midwife. An important Bill was prepared by a subcommittee of the British Medical Association, a Midwives Registration Bill had been introduced into the House of Commons by Mr. Tatton Egerton, and there were two private Bills before the House which represented movements owning considerable support. This variously promoted group of measures may be taken as a proof of complete recognition that pregnant and parturient women in the lower classes were not sufficiently protected from the risks of childbirth. The rates of mortality due to the ignorance and dirtiness of unregistered midwives, many of them old ladies who attended a lying-in or a laying-out with equal relish, were so variously stated that the best informed took refuge in such rough statements as "hundreds of thousands of women die every year from these evils," but no one contested the presence of the evils. Not only were there wide divergencies in the various measures advocated as a remedy, but opinion in medical ranks as to the necessity for the registration of midwives was divided. And those members of the medical profession who were prepared to let things remain unaltered were not displaying either want of humanity or supineness : they believed that under the régime of registered midwives midwifery as a science and art would degenerate and would cease to be kept up to the standard of the great branches of practical medicine and surgery. They also believed that with the registration of midwives the practice of midwifery in normal cases would pass from them, a loss which was not to be measured so much in money as in influence and responsibility. Midwifery practice among the poor was not lucrative, but it brought the practitioner into intimate relation with the home. To a limited extent—and 20 years ago it was limited—the medical man who attended the confinement became aware of the antenatal circumstances, while the after-care of the children devolved naturally upon him. With these things in their mind there grew up among many doctors opposition to the principle which inspired the numerous Bills, as well as a very critical attitude towards each measure.

Accordingly a comparatively large number of practitioners opposed all measures for the registration of midwives, and the agitation lasted some years. Its steps do not require to be chronicled here, but within THE LANCET it had grave consequences. The General Medical Council had come to the conclusion, which no one to-day can think otherwise than a right one, that the registration of midwives was badly needed in the cause of common humanity, while the Senior Direct Representative of the profession on that Council, Glover, was known to be our trusted adviser on questions of public policy and the relations of the medical profession to the public at large. Neither the

Wakleys nor Glover had any hesitation as to which side the paper should take, but the course adopted was not popular with an appreciable fraction of our readers. It was decided to make an attempt to ascertain the general feeling of those medical practitioners whom the proposed legislation immediately concerned. The Bill did not contemplate Scotland or Ireland in its working. We addressed a circular to the English medical practitioners and received a number of replies which was unexpectedly large, having regard to the fact that a large proportion of persons never answer circulars, and that a certain proportion of those to whom our questionnaire was addressed considered the absence of personal interest to absolve them from reply. Over 6000 English practitioners replied immediately, and of these 1817 considered that no legislation was required, of whom 1530 were also and for specific reasons opposed to the Bill before the House; 1323, while opposed to the Bill, desired to see legislation for putting down many of the practices in vogue among unqualified persons; 433 while approving legislation for regulation of the practice of midwives were not in favour of the particular Bill; and 1311 medical men were in favour both of legislation for the regulation of the practice of midwives and of the Bill. Six hundred and eighty-nine medical men did not answer the questions with a simple "yes" or "no," but wrote letters explaining their views, and the analysis of these letters showed that 445 were opposed to the Bill. The total was made up of those who wrote to express indifference to the whole matter, the one thing emerging being that of 6299 medical men only 1311 were in actual favour of the Bill before the House. A little over 1000 belated replies confirmed the proportion of these figures. We like to remember that, although at the time the policy was not one which improved our circulation, we interpreted these figures rightly in believing that they implied far more apprehension of the results of a particular measure than a whole-hearted opposition to the principle of registration of midwives. An Act to secure the right training of midwives and to regulate their practice was passed in 1902, but was severely criticised at the time in our columns. The measure during two years' delay and disputation had been altered in shape and not for the better, but our main opposition to it was that it did not conform to the directions of the Privy Council that certain points should be conceded in deference to the views of the General Medical Council. As we anticipated, many hard circumstances arose under the Act, which was amended in 1918 in favour of the existing legislation.

THE LANCET COMMISSIONS.

A testimonial to the work done by Dr. A. H. Hassall and those who collaborated with him in carrying out the Analytical Sanitary Commissions formed part of James Wakley's dying message. Hassall's share in that work has been described at length, and a series of independent inquiries of all kinds was undertaken for many years on the same pattern, or with the same broad object. The scheme took a permanent form, a chemical laboratory was installed in The Lancet building, and investigations were made on the spot and reported upon in the columns of the paper. As far as the chemical and analytical work was concerned, it was supervised for the 33 years between 1860, when Hassall became only an occasional assistant, and 1893 by C. W. Heaton, who held at different times examinerships in chemistry at the Royal College of Physicians, London, and the Royal College of Veterinary Surgeons, was public analyst for St. Martin's, treasurer of the Society of Public Analysts, and an original Fellow of the Institute of Chemistry. Heaton's first appointment was to lecture in chemistry at Charing Cross, but he had previously been science master at Epsom College, and the two things determined his invitation to join the staff of The Lancet. First, the proximity of Charing Cross made it possible for Heaton to deliver lectures at the Medical School while attending to The Lancet Laboratory, and, secondly, his connexion with Epsom was a very sound introduction. Moreover, Heaton had written, and was writing, scientific articles for the *Saturday Review*, so that as a practised journalist he was particularly well equipped for our post.

But, as important as any of the work done in the Laboratory, were Special Commissions set in motion to inquire into various defects associated with social machinery understood in the broadest way. While Heaton's work may be considered as a sequel to that of the brothers Henry, Letheby and Hassall, the other Commissions were more on the pattern of the inquiry made by Anstie and his collaborators into the Condition of Workhouse Infirmaries or the inquiry into the Conditions and Influences of Railway Travelling.

We can illustrate the range of these inquiries by some of their titles. Analytical Sanitary Commissions were instituted to inquire into Opium and its Adulterations; into the Constitution of Coloured Confectionery, which was frankly termed poisonous; into the Adulteration of Popular Beverages like Porter and Gin.

Inquiries into the character of the food-supply of great cities like Manchester, Liverpool, and Leeds were made on the spot. Other reports, the result of first-hand investigation, dealt with the Water-supply of London, the Hygienic Condition of Aldershot Camp; the Out-patient Departments of Metropolitan Hospitals; the State of Workhouse Hospitals (a second inquiry); and the Sanitary Arrangements at Public Schools, among which may be mentioned Wellington, Marlborough, the Bluecoat School, Eton, Harrow, Winchester, Shrewsbury, Rugby, and Uppingham. Other inquiries dealt with the health of children in large pauper schools, night nursing at hospitals, and the sanitary condition of the chief English watering-places.

Many of these inquiries make good reading now, and the fact that it should have been left to a newspaper to set them in motion is a striking proof of the subsequent growth of sanitation in this country.

It was absolutely necessary that such matters should be looked into for the good of the public health, but inquiries undertaken by a newspaper would have been an intolerable interference had there been properly constituted authorities to undertake the work and shoulder the responsibilities. It is needless to say that the actions of THE LANCET were often bitterly resented, as at Brighton, but the public motive at the back of the work, and its unprofitable nature, ensured the popularity of our efforts. It may fairly be claimed that the revelations made year after year in the columns of THE LANCET inspired sanitary legislation in every direction. This is not to suggest that everyone else was blind to the abuses revealed. Certainly many of our inquiries were made in reply to requests from those who, from personal knowledge, were aware of what would be discovered, while other observers besides the staff of THE LANCET were alive to the fact that legislation along certain lines would abate abuses. But, where the work of THE LANCET was not original, it was at any rate vocal, and when its voice was felt by those affected as a profoundly disagreeable one the necessity for raising it was justified. The last six Commissions instituted by James Wakley, not including his continuation of the inquiries into the conditions of lunatic asylums and sick infirmaries attached to workhouses, were the following: Spread of Disease through Laundries; Contamination of Uniforms Provided by the Army Clothing Depôt; Ventilation of Police-courts, and, later, of the new Royal Courts of Justice; and the Pollution of the River Thames at Henley Regatta. To some of these further allusion will be made.

BRIGHTON DRAINAGE.

Against one of the most famous watering-places in the country THE LANCET appeared to have a grudge, but in the end the community admitted that they never had a better friend than their candid critic. The subject was returned to on several occasions, until all need for interference was gone, and is selected for reference out of the long list given above as an example of the way in which the Commissions were designed to deal with public things in a medical manner, and in a shape that would be useful to other communities than the one concerned.

In 1862 two long and plain-spoken reports were published showing by chemical and microscopical analysis the impurity of the drinking-water at Brighton, and giving full evidence as to the disgusting nature of the contamination to which the front was exposed. At that time three-fourths of the houses drained into cesspools without any outlet, while the sewage from the remaining fourth was thrown into the sea in front of the houses, where it formed an intolerable nuisance. Brighton resented the report but acted upon it, and there was an extension of the drainage system by which the bulk of the sewage was carried a third of a mile east. This was in 1864, but in 1868, it having become clear that the measures taken were inoperative, a further report was published pointing out that the drainage of the town was still imperfect, that the bathing in the front was being fouled in a disgusting manner, that 10,000 cesspools were still in operation, and that only 4000 houses were connected with sewers. A torrent of indignation fell upon THE LANCET from those interested, but the corporation of the city was roused to vigorous action and a resolution was taken to deal at once in a liberal spirit with the whole difficulty. By 1874 a main intercepting sewer had been constructed which carried the sewage to an outfall four miles further to the east, when a second report was made on the drainage conditions of the town. In this, THE LANCET, while offering congratulations to the municipal government upon their action and acknowledging the improvements which had taken place, found fault with the ventilation and recommended further inquiry. As a result, Sir Joseph Bazalgette reported on the sewage of Brighton, when his words afforded complete justification of what appeared to be attacks made unjustifiable by their reiteration. And so at last the great health resort became the splendidly sanitary city it now is.

The Editors of THE LANCET then went to Brighton regularly for the winter months of many years, and thus designedly or accidentally showed their certainty that no more criticism of the drainage was called for. The *rapprochement* was poignant, for at one time many Brightonians spoke loudly of bringing actions against THE LANCET for damage of their house property and businesses, while the Wakleys on their side were only with difficulty restrained from proceeding for libel against certain members of the Brighton town council, who said that the unfavourable reports upon Brighton as a health resort were due to the fact that the Editors of THE LANCET had acquired property in the neighbourhood of a rival health-resort.

THE LAST THIRTY YEARS:

THE STAFF OF "THE LANCET."

IN 1893 THE LANCET was under the editorship of Thomas Henry Wakley and his son, the third Thomas Wakley, and of those mentioned as having conducted the paper during James Wakley's long and fatal illness, Glover was still the principal adviser on medical politics and organisation, and Marston remained to direct our views on Service and other matters with which his long public career had made him familiar, while THE LANCET Laboratory was under the direction of Samuel Archibald Vasey, Heaton's pupil and assistant, who had succeeded him as director. Upon Tweedy's help we could always rely. In this year Dr. Squire Sprigge, the present Editor, was appointed assistant editor, the internal staff being immediately afterwards strengthened by the presence of Dr. H. P. Cholmeley. Beckett was still in regular employ, but a breakdown in his health had made his attendance at the office largely a matter of personal desire to stay in harness, the sub-editor's duties being discharged by the late Dr. W. L. Brown. In the following year Mr. Charles Good became the general manager.

This small internal staff was advised along the obvious lines of general and special work by a body of collaborators of whom the list follows, and the number whom it was considered necessary to call upon for help is a direct revelation of the way in which medical science had recently spread. The external staff in 1893 was four times the size it had been 20 years before; in fact, to-day it is not larger, and for two reasons. First, there are many places in which medical activities have become more concentrated, while running more in accordance with some accepted plan, making it unnecessary to publish certain things either so often or so much in detail. But, secondly, medical science and medical organisation have progressed in so many and such varying ways that no restricted staff, however large, could possibly either record the happenings week by week, or deliver any but the most perfunctory opinions upon them. This has necessitated the regular invitation of particular persons to assist us along particular lines, whereas in 1893 the Wakleys attempted to collect a group of collaborators who showed themselves able to deal immediately with anything scientific or social which should present itself to notice week by week.

The names now given are those of the staff in 1893.

Collaborators in 1893.

The list is taken from an old ledger, whose contents are protected by padlocks, a reminiscence, no doubt, of the sad old times when it was necessary to protect the author of, say, an "Intercepted Letter" or a "Medical Biography" from the consequences of his humour:

*J. H. Barnard, A. Boggs, *E. Bar, Dudley Buxton, W. H. Battle, J. W. Byers, J. H. G. Brock, H. T. Bulstrode, John Curnow, Sidney Coupland, F. G. Clemow, H. Radcliffe Crocker, Richard Davy, C. Duncan, *R. Ellis, W. H. Evans, C. Fleming, A. Pearce Gould, J. W. Gordon, W. R. Gowers, C. Hime, *C. A. Hodgetts, Noel Humphreys, Leopold Hudson, W. S. Hedley, C. J. Huddart, F. W. Lowndes, James Lindsay, A. H. N. Lewers, Shirley Murphy, B. G. Morrison, Theodore Maxwell, A. Macgregor, John C. McVail, A. Napier, David Nicolson, Henry Power, Vivian Poore, A. J. Pepper, *M. C. Prendergast, C. H. Robinson, William Russell, Walter Rivington, Benjamin Ward Richardson, C. H. Ralfe, *F. Ransom, R. D. Sweeting, H. Simpson, Adolphe Smith, *J. P. Steele, *G. R. Saunders, A. M. Sheild, G. A. Syme, F. G. Sandwith, *Stephen Smith, C. Shoveller, Nestor Tirard, James Taylor, John Tatham, G. Thin, F. J. Wethered, E. F. Willoughby, W. Essex Wynter, W. W. Webb, G. Sims Woodhead.

In this list, which at such a lapse of time there can be no indiscretion in publishing, the names marked with an asterisk are those of foreign correspondents, the countries represented being France, Italy, Germany and Austria on the Continent, Egypt, Canada, Australia and New Zealand. A sad number of these have died during the 30 years that have elapsed since the ledger list was compiled, but this, of course, could only be expected; on the other hand, the majority survive, and many of them are still working in a distinguished manner in the profession. We must here record our sense of gratitude for their help, and if it is done in bald or general terms the reasons for avoiding adjectives are obvious. Those who are alive would not desire to be reminded of their merits, while the mere names of many of them will enable a medical public to recognise their worth without any testimonials from us. But there is a group of men among these who must be mentioned in our centenary number with some particularity because of their long and intimate connexion with us. Dr. Sidney Coupland, Mr. W. H. Battle, Mr. Adolphe Smith and Dr. Dudley Buxton, among those who still happily live; and Sims Woodhead, Pearce Gould, Shirley Murphy, Bulstrode, and Vivian Poore, among those who have gone—these were the principal leader-writers or heads of departments for many years, in conjunction with Glover, Marston, Sir John Tweedy, Vasey, Cholmeley, and the present editor. Under the section of Anæsthetics there has been indicated the long and heavy work entailed upon Dr. Buxton, who kept us fully informed upon his own speciality for so many years.

More Old Friends.

Three whose names are in the enumeration for 1893 rendered the greater proportion of their help earlier. From the days of James Wakley onwards their learning and judgment, in widely differing capacities, was a source of pleasure and information to our readers. They are Sir Benjamin Ward Richardson, Henry Power, and James Peddie Steele. Benjamin Ward Richardson (Fig. 38), trained in the Universities of Edinburgh and Glasgow, joined the staff of The Lancet in the early fifties, having been introduced to the first Wakley by Douglas Jerrold. He was physician to many public charities, though not attached to any general hospital. He gained the Astley Cooper Prize and the Fothergillian Gold Medal of the Medical Society of London, and was a great sanitary reformer and humanitarian. He did much original work in anæsthetics, was elected an F.R.S., and delivered the Croonian lectures at the Royal College of Physicians. The most open-minded and generous of men, there was a time when his animosity and that of Christopher Heath to Ernest Hart were embarrassing to the Wakleys, who had no desire to prolong a sterile series of bickerings, and for a period his contributions ceased. His range of general knowledge was immense. He wrote in poetry and prose, and produced practically single-handed a journal embodying researches in the science, art, and literature of medicine, *The Asclepiad*, which as an annual, and later as a quarterly, had a life of over 30 years and contained much interesting and valuable matter. His articles, sometimes signed, but mostly unsigned, in The Lancet dealt accurately with questions of pharmacology and therapeutics, forensic medicine, domestic sanitation, veterinary surgery, and especially the question of total abstinence. He was a convinced teetotaller, but none the less found alcohol to be a valuable drug if competently administered.

James Peddie Steele, also thoroughly trained at Scottish Universities, was known as a scholar in Edinburgh before he came to London, nominally as a physician but really as a journalist. Under James Wakley he was a regular leader writer on the staff, and when, about 1880, he went to Rome and obtained a large and good practice, he continued to write editorial articles, while as our local correspondent in Rome, and later in Florence, he kept the paper closely in touch with Italian medicine. He was a sound classic and a really famous Latinist, and his leading articles, which appeared in some of the best known lay journals as well as in THE LANCET, could generally be detected by their successful use of the old-fashioned Latin period to display an advanced spirit of medical research. On retiring from practice in Rome he went to live in Florence, where his villa became the centre of open-handed hospitality. He was the personal friend of the leaders of Italian scientific and social thought, who had opportunities of meeting at his table representatives of English scientific and academic life. He wrote in these pages until his death in 1917.

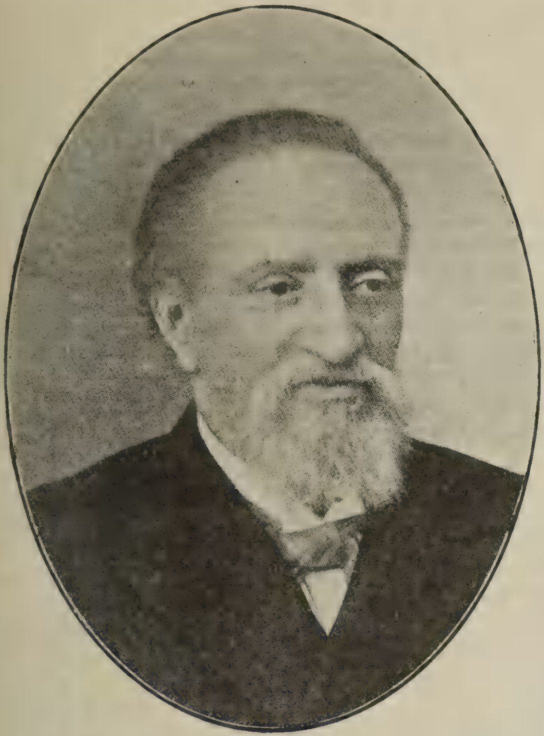

FIG. 38.—SIR BENJAMIN WARD RICHARDSON.

Henry Power (Fig. 39), ophthalmic surgeon to St. Bartholomew's Hospital, was for over 40 years a regular member of our staff. His varied literary work showed well his industry and wide range of exact knowledge, but the particular services which he rendered to THE LANCET were allied to the fact that he edited the sixth, seventh, eighth, and ninth editions of Carpenter's Principles of Human Physiology. He was a really great student of all the manifestations of life. He had read widely and in several languages anatomy, physiology, and botany, and week after week and year after year in our columns he summarised continental knowledge of these subjects or sat in genial judgment upon medical writers, when so closely accurate were his appreciations, and so obviously fair and friendly his reservations, that no author was even moved to protest against his criticisms. No member of the staff of THE LANCET was ever more missed than Henry Power when retirement from London broke his intimate association with us.

Gowers, the author of the "Manual of Diseases of the Nervous System," was a great investigator and observer as well as a successful expositor of the theories of Hughlings Jackson. He wrote largely in our columns both editorially and above his signature, and was not an easy man to work with. While he was an extraordinary observer with a wide horizon and sound judgment his sweeping deductions, preceded by no exposure of reasons, were embarrassing, and when the consequent obscurity was pointed out to him he disliked the process. But in a difficult field of medicine Gowers kept us well informed, and it was through his intervention that Hughlings Jackson's delightful series of "Neurological Fragments" appeared in our columns for many years—veritable chips from the workshop of a master mind. But before the "Fragments" appeared we had published many of Hughlings Jackson's important communications in our columns, the two last illustrating well the range of this remarkable man's work. The former dealt with eye symptoms in locomotor ataxy, and the second was an address on the psychology of joking in which a solid and unpretentious philosopher defended with great humour the value of punning. His argument in his own words is :—

"I say that the process of all thought is double, in degrees from a stereoscopic unity of subject and object to manifest diplopia (two objective states for one

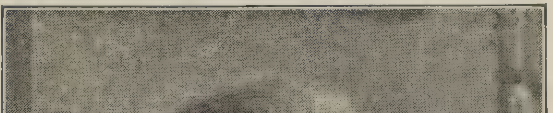

FIG. 39.—HENRY POWER

subject). The process of all thought is tracing relations of resemblance and difference from simplest perceptions—to say what a thing is, is to say what it is like and unlike—up to most complex abstract reasoning. The formula of the charicature of the normal process of thought is the 'pretence' of some resemblance between things vastly different—from punning where the pretended resemblances and real differences are of a simple order, up to humour where both are highly compound. We have the 'play' of the mind in three degrees of evolution, three stages of exceedingly complex incongruousness." (Fig. 40).

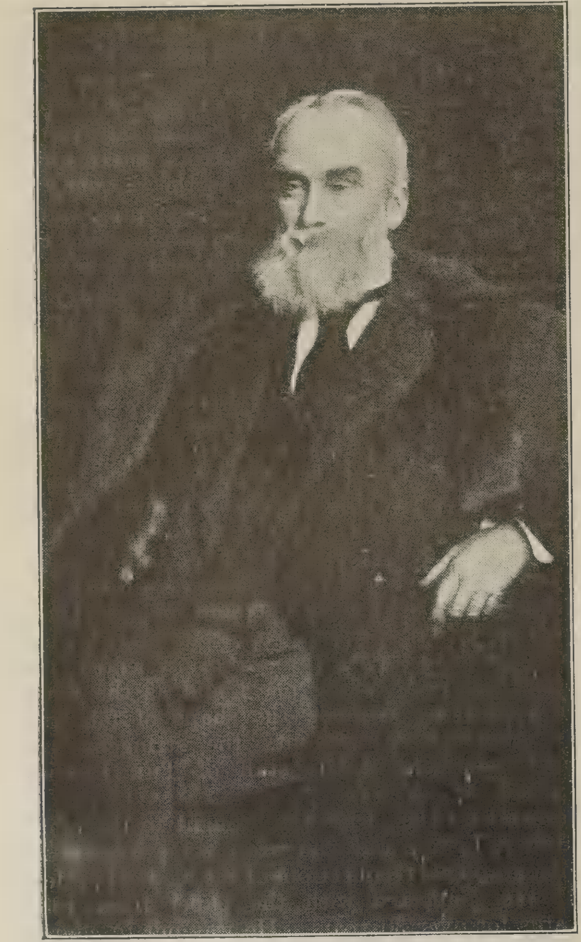

FIG. 40.—HUGHLINGS JACKSON.

For an extended period Dr. Coupland was our general adviser in clinical medicine, until he was succeeded by Dr. F. J. Wethered on his appointment to a Commissionership in Lunacy. A cursory view of the matters that came before him is furnished by the résumé of clinical progress in the 'eighties, and no member of the staff was more frequently consulted, or called upon to formulate early opinions upon new departures. Mr. W. H. Battle was the editor of the Mirror of Hospital Practice (of which more will be said briefly), while the late Sir Alfred Pearce Gould became the principal leader-writer on surgical subjects ; Vivian Poore wrote regularly in an editorial capacity on medicine in connexion with public health, and the early articles on electro-therapeutics were from his pen ; Dr. Dudley Buxton's exhaustive summaries of the developments in anæsthetics, and Sims Woodhead's similar treatment of bacteriology, enabled us to keep our readers up-to-date in two sections of medicine that were at that time progressing in different and highly technical ways. Bulstrode and Shirley Murphy were our advisers on public health on such terms as their official positions permitted. To both THE LANCET was and is under unpayable obligations. To recall here the manner of man that Shirley Murphy was would have a flavour of impertinence, so recent is his death and so widely known his surpassing merit as a sanitarian. But Bulstrode is in different case. He was in full exercise of fine qualities as administrator, technical adviser, and scientific investigator when he died suddenly. He was permitted by his chief, Sir Richard Thorne Thorne, to keep THE LANCET advised on public health matters, and his clear articles upon situations as they arose were of special value to our public.

THE INFECTIOUS DISEASES NOTIFICATION ACT.

As an example of Bulstrode's work, and also of the endeavours of THE LANCET at the time, there may be adduced a series of editorial articles upon the difficulties which arose under the Infectious Diseases Notification Act. The Act came into being in 1889, but its working was found difficult not so much because the measure was unpopular with the public—though it was that—as because a strained position arose between the private practitioners and the State officials. This became quite serious, and time did not relieve it. In 1895 we were so frequently asked to advise correspondents in difficult and delicate positions, that it was decided to collect together in one set of articles the principal points as to which procedure was doubtful. It seemed certain that actual misunderstanding on both sides was occurring alike as to the meaning of the Act and the spirit in which it was interpreted, and Sir Richard Thorne Thorne, then Principal Medical Officer to the Local Government Board, desired to have the various matters thrashed out. Accordingly we placed on record in Bulstrode's articles the various decisions and official interpretations which had been given with regard to difficult points, and reading those articles now we can see that neither the medical officers of health nor the general practitioners were at first quite certain what new obligations had been imposed on them. For example, some local authorities believed that the Act laid the duty upon the medical officer of health to make domiciliary inspections, and when many of these officers realised that the Act put no obligation of the sort upon them they found that neglect to perform it was quoted against them in questions of adjustment of salary. And in those days the tenure of office of medical officer of health was far more precarious. The situation was set right by a definite statement of the Local Government Board that the Infectious Diseases Notification Act of 1889, where adopted, conferred no new powers upon the medical officer of health, being "designed to afford him such immediate information of the outbreak of infectious diseases as will enable him promptly to take such measures as are prescribed, &c." This Order made it clear to the local authorities that where an outbreak of any contagious or infectious or epidemic disease of a dangerous character had been notified it would naturally become their officer's duty to make personal inspection, but that he was not expected or desired to make domiciliary visits.

The advice given in THE LANCET with regard to domiciliary visits shows well how delicate the relations on the passing of the Act had become between the State officer and the private practitioner. Stress is laid on the fact that in the majority of instances in which cases of infectious disease have been notified there is no need for the medical officer to personally inspect the sick chamber, while this should only be done with the consent of those having charge of the patient and after securing the coöperation of the general practitioner. Throughout all the articles it is urged upon the medical officer of health to use the help of the medical practitioner in attendance on the case, and the same principle, it is pointed out, should be extended to the inspection of premises. In short, the view is strongly held that the customs usually governing the relations of medical practitioners to each other should prevail between the medical officer of health and the general practitioner. Our articles stated that it was not the intention of the Act relating to notification to lead to the visiting and examination of sick persons in ordinary circumstances, in spite of the fact that public health authorities might consider such measures to be the only way in which the correctness of certificates of notification could be ascertained. The Local Government Board upheld our view, whose correctness was indicated by the fact that no increase of salary came to the medical officer of health by the passage of the Act, implying that the duties of a private practitioner were not to be added to the public responsibilities. The general conclusions arrived at are worth recording, for they show the places where disputes had arisen, and may serve as a useful reminder to legislators how inexpedient it is to pass laws without ascertaining from those who really understand professional situations how far ambiguity of words or meaning may lead to mystification.

The conclusions, which at once settled much disputing, were :—(1) The question of a personal visit by the medical officer of health is a matter to be decided by the medical officer of health, he being the judge as to what constitutes an "outbreak" for the purpose of the Order relating to his duties. (2) No duty attaches to a medical officer of health to "visit . . . the spot" in every case of notified disease. (3) When he deems it his duty to pay such a visit he should remember that, apart from a magistrate's order, he cannot claim a right of entry on such ground. . . . (5) The medical officer of health has no right to inspect patients, and, as such inspection is, as a rule, very undesirable, it should not be contemplated even when it is necessary, except after communication with, and if possible in coöperation with, the medical officer in attendance on the case.

THE MIRROR OF HOSPITAL PRACTICE.

There are many instances in which certain features of THE LANCET which had been introduced to meet the wants of the time, and which had flourished bravely while those wants existed, disappeared from our columns when the purpose for which they had been planned was met. There was no department of THE LANCET in the early days, when its scope was decided upon, of which there was more reason to be legitimately proud than that entitled, "The Mirror of Hospital Practice." This department was the outcome of the intention, forming part of the first programme of the paper, to publish what went on inside the walls of hospitals, the underlying, and sometimes the avowed, idea being that it was necessary to let in light upon dark places. It follows that at first those who discharged the duty of attending the hospitals with a view to report hospital life, remained strictly incogniti, and especially was this necessary after the frankly libellous tone in which the first articles were written. Many of the early reports were furnished by members of the staffs of the various hospitals, and sometimes by the residents and assistants, who realised the need of radical reform, saw that it would follow upon plain speaking, but could not be expected to disobey the strict injunctions of their seniors openly. There is no doubt that the improved tone of the comments upon operative procedure reflected the reforms that were taking place, and as the notes upon operations assumed the shape of fair and often appreciative accounts the stringent ban against members of the staff of THE LANCET was lifted.

Fernandez Clark, who was brought to the office by Robert Liston, and who wrote some interesting autobiographical recollections of the medical profession, was connected with the paper from 1834 onwards for over 30 years. He was put in charge of "The Mirror," and his accounts of operations at the hospitals were frequently supervised by the surgeons concerned. The anonymity of his other collaborators and his more immediate successors has been so faithfully kept secret that to-day no one can recall their names. When in 1872 Tweedy became the editor of "The Mirror" circumstances had much altered. At all the hospitals the representative of THE LANCET was made welcome, save during that unlucky period, to which allusion has been already made, when a London consultant surgeon was made the subject of an unjustifiable attack. Our relations with the staffs of hospitals were then, for a time, made difficult, and only the tact and popularity of the editor of "The Mirror" re-established them again on a pleasant footing. We need only mention the last two surgeons who edited "The Mirror" to show how important a section of the paper it was considered. They were Sir John Tweedy and Mr. W. H. Battle, who resigned in favour of Mr. Willmott Evans just before that section of the paper was discontinued. Mr. Battle assisted us in this way for ten years, and his pithy comments upon the questions arising from the reports he was making were very instructive. We may give as an example the notes upon the operative treatment of abdominal diseases at a time, be it remembered, when methods in common vogue were giving unsatisfactory results. Readers were encouraged to try new and generally bolder plans in cases, for example, of "acute abdomen" and intussusception, by having before them a summary of cases under other surgeons.

But it was Mr. Battle himself who pointed out that the purpose for which the department was founded had ceased to have its original significance. First there was no particular reason to send a representative of The Lancet to the hospitals when the staffs of the hospitals were willing to communicate their interesting cases without an intermediary, and when all idea of detective work had vanished. Secondly, the enormous growth of operating had reduced to a perfectly ridiculous point the possibility of any representative of The Lancet being present at the right hospital at the right moment to see the right operation. When "The Mirror of Hospital Practice" was started the large hospitals had a day set apart for operations, and save in cases of emergency the patient to be operated upon was prepared for the ordeal on that day. At a large metropolitan hospital the major operations for the whole week, excluding the emergencies, were often performed between two and half-past four on a particular afternoon. Then at the larger hospitals two afternoons were set aside for operating; and at last, in response to the enormous progress made in surgery, operations became a part of the ordinary procedure of the hospitals, and there was no possibility of any representative of The Lancet being certain of seeing any really new departure. The editor of "The Mirror" was often informed by intending operators of a procedure they desired to take which appeared to be of a radically new nature, but even so it was usually preferred to leave the drawing up of the full report to the operator. Further, the general outlook of scientific surgery had so altered that a surgeon often no longer wished to record a single operation. His work he felt had been done in association with that of others and he preferred to allow it time for collation. The real meaning of modern surgery would have escaped comprehension in records of isolated events.

The Doom of the Unqualified Assistant.

In 1893 there were a good many scandals in connexion with the improper use of unqualified assistants by medical men. The unqualified assistant was a survival of the old days of apprenticeship, when a medical man took under his care and very frequently into his house a commencing student, whom he instructed in the principles and details of practice, the time so spent counting in the lad's educational curriculum. The Medical Acts had done away with apprenticeship, and although return to it was advocated by many, no advantages could ever be claimed for it commensurate with its drawbacks. It was felt that it would be fatal to an educational system, now rationally arranged, to admit a scheme which left so much to chance. Setting aside the question of whether empirical training in therapeutics before the acquisition of a scientific ground-work can ever be valuable to the better students, apprenticeship left it to chance whether the tyro obtained any instruction worth having. He learned to dispense up to a point, he was present at a certain number of labours, he was taught to vaccinate, but not well taught, and perhaps became familiar with some form of book-keeping. Unless, however, his time was spent in a manner that constituted something of a public abuse—that is to say, unless he practised as a general practitioner, without a qualification and covered by a principal—his occupation could not have been of service to him after the medical schools had regularised their educational courses in conformity with the Medical Acts.

But in many cases he became his master's unqualified assistant, and by developing the duties of the surgery attendant into those of the general practitioner he grew to be an undeclared partner in the practice. He was paid by salary—low salary—and not as a partner, but the public had no doubt whatever of his status as a qualified man. The supply of apprentices dropped off as the medical curriculum was properly arranged, when their place was taken by unqualified assistants, who for the most part had given up the idea of obtaining a place on the Register, but who had in many cases done a full course of medical training. Their employment was frequent all over the country, and where supervised their services were of great value both to their employers and the public. But unfortunately grave abuses began to arise. Some doctors left all their club practice and much of their midwifery to such assistants, and the public did not obtain the quality of service which was being paid for. And in large cities multiple practices began to be run by these unqualified men. They were the employees of one registered practitioner, who covered their activities, and, perhaps to the prejudice of neighbouring colleagues, took their earnings. By 1897 the position had come so prominently before the General Medical Council that measures were taken to set the whole matter right. The Council resolved with practical unanimity to state clearly that the employment of an unqualified assistant, save in the form of a pupil, would be considered by the Council as "infamous conduct in a professional respect," to be punished by removal from the Register. The cases of abuse had many of them been reported in The Lancet, where the action of the Council was anticipated, but the immediate result was very hard upon an unfortunate class, and we were found deploring the precipitancy of the reform while approving its object heartily. Undoubtedly a very large number of our supporters were seriously embarrassed by the necessity of dispensing with services which they valued highly, and which in many instances were wisely directed and controlled to the benefit of the public; they were disappointed that we were compelled to approve of a measure of reform which, as a matter of fact, was designed to meet unprofessional situations which had been described in our columns.

Of the main decision of the Council we entirely approved. It was a complete anachronism that half or a third of the work of the medical profession should be done by persons not in the strict sense of the word medical practitioners. Such an arrangement was deceptive as regards the public who thought they were getting the advice of qualified persons, and grossly unjust towards young practitioners who should find their first and most valuable work in the field of private practice under the supervision of an intelligent and experienced principal. The General Medical Council did its duty by legislating for the suppression of all inferior and unqualified forms of practice, and those who had the interests of the medical profession at heart recognised this and applauded its action. May we add that our old friends returned.

THE BATTLE OF THE CLUBS.

Exactly when the conditions of contract practice began to be felt by medical practitioners as thoroughly unjust and to be recognised by the more intelligent of the public as inefficient it would be hard to say. The old-fashioned club practice did not break down at any particular date in any universal way. On the contrary, in communities which it suited and in hands where contract practice was sympathetically and intelligently treated, there were circumstances about it which gave it considerable appeal both to the practitioners and to the patients. But this was mainly in rural districts where the mass of patients affected was much smaller, and where close relations between the doctor and his charges were better preserved. In the larger towns, and in connexion with workshops, where masses of operatives were aggregated, the rules and customs under which doctors were accepting capitation fees for medical attendance were often thoroughly oppressive.

If there is one date more than another when a general movement against contract practice came to a head, it occurred in December, 1895, when the medical men of Cork took the decisive step of forming a benefit club to be managed entirely by themselves. The issues at Cork were exceedingly simple. Large tradesmen, well-salaried clerks, and bank managers had joined medical clubs, and were demanding to be treated upon the same terms as the artisans and the labourers, and in some cases it was attempted to make small yearly fees cover attendance, in addition, upon every member of the subscriber's family. The medical officers of the clubs protested, found their protests unavailing, and resigned. The clubs retaliated by importing new medical officers into Cork. The medical profession of Cork rallied round the dismissed officers, and the students proceeded to infuse liveliness. The medical men concerned met delegates from the clubs at a conference at which free acknowledgment was made that the medical profession had substantial grievances, and the hospitals of the city were drawn into the battle. While this dispute was receiving considerable attention in the lay papers, the letter-bag of THE LANCET was swelled with stories of similar treatment meted out to the profession at other centres, and we decided to make an immediate inquiry into the position of the medical profession in regard to the numerous societies which in certain districts were providing medical aid for the sick poor.

These societies were increasing in number, and the hardship to the general practitioner was growing in proportion. Mr. Adolphe Smith was commissioned by THE LANCET to make an inquiry on the spot at a wide variety of representative centres. Large cities and small manufacturing and agricultural centres, a fashionable health-resort, a populous port, and a cathedral city were selected as forming types from which information should be collected for purposes of sifting and comparison.

It was soon seen that different orders of clubs or associations had to be dealt with. There were societies having as their primary objects schemes for life assurance only, adding to them a project for medical aid as an inducement to the public to enter their fold. Others were constituted with the simple intent to secure for the public medical attendance at low rates, which was an excellent programme if it could be carried through without oppression of those who rendered the attendance, but their object was already largely met by the sick-clubs managed with great capacity and thoroughness by many practitioners. Some of the societies were well organised, in that an effective attempt was made to ensure that only the truly necessitous were the recipients of medical charity. Others were uncommonly ill-managed, in that all persons, no matter what their condition of health might be, or their means, were invited to enrol themselves that they might be treated medically for a penny or two a week, drugs included. The profits made by these companies, though earned by medical work, never, or hardly ever, found their way either to medical men or medical institutions. In certain of the institutions, the management of the association having been and remaining entirely in lay hands, the interests of the medical officers suffered severely. They were badly treated by the persons to whom they dispensed charity, their emolument was small, their work was hard, and the patients who could reasonably have been expected to pay them as private clients were systematically exploiting their services.

Mr. Smith's reports were published in THE LANCET week by week, when the conclusions which were come to proved clearly that the whole system of contract practice as existing in the country at that time was riddled with abuses. Sporadic improvement undoubtedly followed the publication of Mr. Smith's articles. It was seen from their general tenour that the lofty view taken by certain members of the medical profession that it was disgraceful to be the medical officer to a medical aid association was not endorsed, while the principal recommendation was that medical men in each neighbourhood where the club system was replacing the practitioner's private sick-clubs should meet and arrange upon a common course, when the situation could be considered from every side. In fact, the conclusions come to had much in common with the arguments lying behind the interim report (Dawson Report) of the Medical Advisory Committee to the Ministry of Health, though the principle of national insurance was not thought of as a practical means for unifying the interests of the medical profession and the public. The articles were issued as a pamphlet, entitled "The Battle of the Clubs," and when Mr. Lloyd George, as Chancellor of the Exchequer, introduced a measure for national insurance into the House the facts put forward in them were much quoted by his supporters and his critics, and more than occasionally the conclusions were perverted by both while feeling was running high.

Some Generalities.

Perusal of The Lancet during the 20 years which preceded the war, that is to say during the first two-thirds of the period under notice, demonstrates the many directions in which the conditions of life had altered and were altering all over the world. The war is generally spoken of as having introduced a new order of things, bringing as its sequel interrelations of peoples, mental states, conditions and prices, which rendered former theories of sociology false or unworkable. On the analogy of medicine it may be surmised that many of the changes under which we are now living had begun before the murder at Sarajevo, and that the effect of the war was sometimes to confirm, and sometimes to modify, a train of events which had already started.

During the 20 years in question there were held International Congresses of Medicine as a whole, British and International Congresses on Tuberculosis, Congresses of Surgery and Hygiene, and at these there were discussed many of the problems which now assail us. Endocrinology became an important subject in therapeutics, and at this moment opinion is divided upon points which presented themselves 15 years ago. The passing of a Vaccination Act in 1898 permitting persons to contract out of a safeguard in public health was a set-back to scientific medicine in our opinion, and to-day the same arguments are being used in support of, or in opposition to, a conscience clause. But there is far more evidence upon which to discuss these things, and absence of the old dogmatism which denounced as quackery or heresy anything done by those of dissentient opinions.

Great changes were effected in the conditions of service for military medical officers, and the naval medical service was much improved, but in neither case have painstaking attempts to meet the requirements of candidates succeeded in their main object. It is clear that here a situation which seems to have been considered over and over again from every point of view still awaits reform. The South African war taught us many lessons of military hygiene, and the extent to which civilian medical men were drawn upon proved that if we were involved in a greater and grimmer struggle the Royal Army Medical Corps, as constituted in 1898, would form but a handful among the doctors required. The Territorial system took note of the position. The South African war gave an opportunity, which was not fully taken, to demonstrate the extreme value of Sir Almroth Wright's researches. Anti-typhoid inoculation forms a grand chapter in pathology which can be read fully in The Lancet, and the adoption of the process by the army in 1906 was a prelude to the saving eight years later of untold lives.

Our knowledge of syphilis was incalculably advanced by Schaudinn's discovery in 1906, which was followed by the Wassermann test, and Ehrlich's introduction of arsenic preparations in treatment. With a definite causation and a new line of therapeutics organised control of the disease started, and immediately it was seen that certain procedures, deemed by many medical men and a large public as essential to success, would be condemned by others, medical and lay, as contrary to public morals, and possibly not as valuable as they appeared. The disease-rate was affected recently by the world-war, but the measures taken for control are proving efficacious to some extent, and differences of opinion are being laid aside.

The ravages of venereal disease shared with those of tuberculosis and cancer the dismal honour of being more written about in our columns during this period than any other subjects, and in the matter of tuberculosis, as in that of syphilis, the measures for mass treatment had started before the war. The King Edward VII. Sanatorium was founded in 1903, at the time when a controversy was raging as to the relation between bovine and human tuberculosis. Many of the questions which were then discussed are still unsettled, but perhaps more than any one thing the incidence of tuberculosis, so dependent upon such varying social circumstances, made clear to the public that the strong advocacy of the institution of a Ministry of Health was necessary. The question came to the fore under many guises, when legislation in respect of housing, of the notification of disease and its institutional treatment, of the tenure of sanitary appointments, and of the safeguarding of children—to take a few obvious examples—were under discussion, and the Ministry arrived in 1919 (see p. 763).

The subjects thus cursorily set down indicate that during the 20 years before the war the writers in The Lancet were dealing largely with things which to-day are as topical as they were then. The war has altered the proportion of their interest, perhaps, and has made measures, that were not then considered, either easier or harder to introduce. But of one thing there can be no doubt. The public has become far more alive to the perils of unqualified practice. During the 20 years we have passed under notice these were particularly widespread, and the revelations in The Lancet of some of these, notably of abortifacients, were of real public service.

An Unpleasant Experience.

At the beginning of the year 1908 The Lancet had the unpleasant experience of unsuccessfully defending an action for libel. It was an expensive experience, for the case lasted several days and eminent counsel were engaged on each side. The action arose out of some comments which were made by THE LANCET upon the words of a coroner, who stigmatised a certain kind of dealing as a fraud. The inquest was reported in a well-known London paper, and the circumstances were made the subject by us of a general denunciation of quackery. The jury, with the hearty approval of the bench, took 20 minutes to agree that our article did not constitute fair criticism, but was an attack on the plaintiff's character. For the information of our readers, and in proof of our perfect good faith, we published the proceedings at full length in our issue of Feb. 1st, 1908. The case is worth reading. Our legal position in appealing against the verdict would have been one of considerable legal complexity, and in the end it was decided not to do so. Therefore, to complain of the issue would have been childish then, as now, but the Editor did not understand by submission to a verdict which surprised him and our readers much, that attention could not be drawn to our position, that is to the necessity that a journal having the objects of THE LANCET, and receiving the support which it did from the medical profession, should take the attitude that was taken, whatever errors in detail might have been committed. It was clear that medical practice of the kind which was fully admitted to have occurred, by whatever word it was designated, must be condemned by the medical profession, and therefore by a journal taking up the position of speaking for that profession. If the situation arose again, warned by experience, we should employ expressions not so easily open to challenge. We had many urgent recommendations to appeal against the verdict, and our legal advisers were not adverse to such a course, while many members of the medical profession suggested the institution of a subscription as a guarantee against further expenses. The Editor was perfectly clear that, if we proceeded to appeal, he would be at the necessary expense himself, but in the end it was decided not to appeal. For the paragraph as written contained an indefensible inaccuracy, and this, in the case of a new trial, would have remained as an embarrassment in discussing the really important features of the case.

This was the first libel action which THE LANCET had lost for a very long period, and, as plain speaking had offered many opportunities for legal rejoinder, the fact should be recorded that, for nearly 90 years, our interests were watched over by the same firm of lawyers. Henry Sandford, who died in 1919, aged 86, was the senior partner of the firm now styled Potter, Sandford and Kilvington. This firm had charge of all the serious legal embroilments which characterised the first ten years of the life of the paper, and at that time included a cousin of the first Thomas Wakley.

THE PRINTING DEPARTMENT.

The old associations have been similarly preserved in the printing department of the paper. At the earliest stage a printer's boy, James Lionel Kerslake, in the firm of Savill and Edwards, used to hold a candle at the tall desk where the Editor was correcting proofs, at a period when gas had not been introduced. He entered the employment of THE LANCET when the paper was set up—as it was for three-quarters of its life—on our own premises; his son-in-law, Mr. William G. Martin, became our head printer; and after 25 years' service in that capacity was succeeded, in 1915, by Mr. Frederick W. Martin, his son, and our present head printer.

THE THIRD THOMAS WAKLEY.

On March 5th, 1909, almost exactly two years after the second Thomas Wakley had died at the advanced age of 86, the son followed the father to the grave in his fifty-eighth year. The third Thomas Wakley was born on July 10th, 1851, and was an only son. He was educated at Westminster and at Trinity College, Cambridge, and at school distinguished himself alike in work and games. He obtained a leaving exhibition, when his father did a graceful action that might well be followed by other parents possessing the means in similar circumstances, for, while desiring his son to keep the prestige which he had won, he forwarded to the boy coming next in the competition a cheque of the value of the leaving exhibition which he just failed to attain. It was no secret to those who knew "Young Tom," as everyone called him to distinguish him from his father, that his resolution to enter the medical profession and follow the footsteps of his forbears was not dictated by choice, and while at Cambridge, and after passing the first M.B., he definitely relinquished the idea. The association with the paper, however, proved too strong for him, and when he was 30 years of age he entered as a medical student at St. Thomas's Hospital and qualified as L.R.C.P. Lond., which in 1883 was definitely a double qualification, though he did not proceed with the medical curriculum at Cambridge. The reason for his late entry as a student was a serious illness following a bicycle accident. For some days his life was in danger as the result of a slight fracture at the base of the skull, and when slowly restoration to health was established it was found that the sight in his right eye was permanently damaged. Immediately after qualification he entered the office of THE LANCET and began the life of a journalist under the tutorship of his uncle and under the eye of that informal sort of editorial committee, already described, which aided James Wakley in the conduct of THE LANCET and took over his responsibilities during his last illness. For three years he profited by such routine duties, and when in 1886 James Wakley died, Thomas Wakley and his father, who had become the proprietors of the paper, worked together in its conduct, as has been already narrated. They made a good combination because their conceptions of duty were so absolutely alike while their methods were at variance, the elder being always young and impetuous, the younger being always deliberate.

One who worked daily with the younger Thomas Wakley for 16 years has written of him as follows :—

> "He strove above all things to be fair, and nothing gave him greater pain than the inability to prove to the man whose views he could not take or whose letters he could not insert, that a sense of justice, arrived at by considering larger issues than had presented themselves to the mind of his correspondents, alone prevented publication. He was also tender-hearted, and many a little flout and jeer, legitimate enough, perhaps, but unnecessary, was removed by his editorial pen because he feared that pain incommensurate with the offence would be inflicted. Lastly, he was extraordinarily accurate, he could bring a good memory to bear upon minute details, with the result that no article passed through his hands without a severe test of its qualities. He wrote but little himself in THE LANCET, as he held that it was exceedingly difficult for a man who wrote not to take a side. The more absolutely unprejudiced a writer holds himself to be, according to Wakley's belief, the more probable is it that unconsciously he will lean to a favourite view or will suggest a policy for trial in particular issues that is in accord with the general character of his own disposition, but not necessarily in accord with the demands of the situation. Distrust of anything like enthusiasm, which is thus implied, was a marked quality in Thomas Wakley, but when he was convinced that the right cause demanded plain speaking, he welcomed that speaking and preferred it eloquent."

In the *British Medical Journal* the following appreciation would have given its subject great pleasure :—

> "It would not be exactly our province to estimate Thomas Wakley's career as a journalist further than to say he worthily maintained the honourable traditions of the great journal whose fortunes he was called upon to direct. But there was one side of his work to which we desire emphatically to bear testimony. The fairness of mind for which he was so well known among his friends led him into relations with ourselves of a particularly pleasant sort. As a result both journals came to recognise that while keen rivalry was the best incentive to enterprise, such rivalry in no way precluded the existence of cordial good feeling between those responsible for the two journals. He was a man who by speech and manner inspired absolute confidence in his straightforwardness, and longer experience only proved that this was the root quality in his character. His word was his bond and he was constitutionally incapable of a mean action."

Outside his editorial work Wakley was a keen and enthusiastic Freemason and an able numismatist, and possessor of a valuable collection of coins.

THE CLOSE OF THE CENTENNIUM.

WHILE this issue of THE LANCET was passing through the hands of the printers one compositor inquired from another, "How big is this Centenary Number going to be ?" and received the advice that he should "look how big it was last time." We see no reason why 100 years hence the advice should not be followed, for in reaching the last stage of a history of 100 years of effort we find evidence of a vitality we wish not to talk about, but which we hope is clear to others.

THE CHANGE OF OWNERSHIP

The third Thomas Wakley married late in life, and his only son was but an infant when he died. No male Wakley had a share in the property or was either a medical man or a journalist, and the paper passed into the hands of a private company. Dr. Squire Sprigge was appointed Editor in succession to his late chief. Dr. H. P. Cholmeley continued as assistant editor, and S. A. Vasey was in charge of the chemical investigations. Mr. Charles Good remained as general manager. Dr. Cholmeley retired in ill-health, from which he has happily recovered, and his place was taken for a period by Dr. N. G. Horner. Dr. Cholmeley, the author of "The Life of John of Gaddesden," had been on the staff of the paper for 13 years, and his retirement was deeply regretted. His wide knowledge ran along unexpected paths, and his impatience of ignorance was veiled in his editorial articles by the facile employment of classical analogies. No one was ever by temperament less adapted for journalism than Cholmeley, but he worked in a routine that never was congenial with an air of amusement at himself and everyone else, and the occasional articles which to-day appear from his pen have all their old charm. Dr. E. C. Morland became assistant editor in 1915.

The present Editor is Sir Squire Sprigge ; the chairman of the Company owning THE LANCET is Sir Ernest Hodder-Williams, and the general manager is Mr. R. E. Sare. We will not detail the names of the staff. In the earlier narrative the identity of collaborators formed part of the history—indeed, their personalities have largely made up the history. At a middle place the names of the staff were given as the readiest way of showing that while the developments in science were of a certain scope, we had friends who could meet our needs in each direction. And at this closing place we render in the warmest way thanks for the general and generous manner in which workers on all scientific and administrative lines place their wisdom, for the most part anonymously, at the disposal of our readers. Without such aid, given week by week, it would be impossible to record progress. They had, as has been shown, much ground to cover. Nor is it necessary to call attention to individual communications. The original articles at this point form an integral part of modern medicine, whose story we and many contemporaries, with general or special purview, are trying to tell, and the writings can be consulted easily, the messages being in many instances familiar.

The impossibility of summarising the scientific contents of the paper was recognised in speaking of those contents as they presented themselves 30 years ago, and the impossibility remains. This chapter of medical history must confine itself to two things, as they are reflected in our pages—namely, the evolution of the profession, and the part played by the profession in public events and the war, with certain points in the domestic life of the paper.

THE NATIONAL INSURANCE ACT.

The year 1911 was memorable for the most important measure of social legislation ever attempted in this country. On May 4th there was introduced in the House of Commons a Bill to provide for Insurance against Loss of Health and for the Prevention and Cure of Disease, containing 115 clauses and 9 schedules, and having emerged in this form complete and perfect from the fertile brain of the then Chancellor of the Exchequer. Its general principles meeting with wide approval, the second reading was agreed on without a division on May 29th, and on Dec. 16th the National Insurance Bill received the Royal Assent and became an Act. During this brief period of eight months no systematic review was possible of a measure at once so complex and unprecedented, the House of Lords remaining content with mere improvement in drafting, while the medical profession was rent by conflicting interests and quite unable to secure effective consideration of the grave principles involved. Time after time THE LANCET insisted upon the grave danger of forcing through without adequate discussion a scheme which proposed to improve the public health by a vast extension of club practice. The British Medical Association took in hand the task of formulating the minimum demands which must be conceded by the Government before the medical profession could cordially coöperate in working the scheme, and a mass meeting of the medical profession, held at the Connaught Rooms on June 1st, set out the six cardinal points around which all further discussion centred. These points were in brief:

1. An income limit of £2 a week for those entitled to medical benefit.
2. Free choice of doctor by the patient, subject only to the consent of the doctor to attend him.
3. Medical and maternity benefits to be administered by Local Health Committees and not by friendly societies.
4. The method of remuneration of medical practitioners adopted by each Local Health Committee to be according to the preference of the majority of the medical profession in the district.
5. Medical remuneration to be what the profession considers adequate, having due regard to the duties to be performed and other conditions of service.
6. Adequate medical representation among the Insurance Commissioners, in the Central Advisory Committee, and in the Local Health Committees, and statutory recognition of a Local Medical Committee representative of the profession in the district of each health committee.

The turning point in the negotiations was undoubtedly reached when, at the invitation of Dr. Addison, Mr. Lloyd George attended a session of the Representative Body of the British Medical Association and declared his conviction that the whole-hearted support of the medical profession was the first condition of the success of the Bill. He then spoke in favour of the principle of free choice of medical man, the vested interests of existing club doctors being respected, and of the appointment of a medical man as one of the Insurance Commissioners; he expressed his personal preference in favour of the freedom of medical men from the control of the friendly societies, provided that the medical profession succeeded in persuading the House of Commons to vest all the charges for medical benefit in the Local Health Committees. Mr. George pointed out that the rate of payment was elastic, as the Bill did not dictate the conditions, and he concurred that payment for work done might be tried as an experiment throughout the district of any Local Health Committee which agreed upon it with the local medical profession. While he held out no hope with regard to an income limit for wage-earners, Mr. George was willing to support the exclusion of voluntary contributors above the income-tax limit, and with a few graceful parting words he acknowledged a reception which had been thoroughly cordial.

During the autumn the stand of the medical profession was transferred to some extent from the cardinal points to a more general demand for just treatment, while the actuality of the Government's willingness to have influential medical opinion represented on the Insurance Commission was more than proved by the dramatic appointment, as deputy-chairman of the Commissioners, of the medical secretary of the British Medical Association. Although THE LANCET felt the danger that by the Act it was proposed to buy the profession of medicine outright at the lowest possible price, nevertheless, it was pointed out in our columns by a careful critic that the prices asked for practices in our advertisement columns were steadily rising, whereas the effects of the Insurance Bill should have caused a rapid fall of value, especially in cash practices. The end of the year was marked by the enthusiastic protest meeting at Manchester at which it was decided that to meet the situation members of the profession should refuse to form a panel under the Bill or to take any duties which the Bill proposed to assign to them, and at this point a National Medical Union was formed to strengthen the hands of the British Medical Association in safeguarding medical interests. At the final passage of the Bill in the House of Lords, Lord Haldane, who had charge of it, frankly expressed his assurance that there would be no difficulty in getting doctors to do the work, inasmuch as it was often extremely tedious for young medical men to secure a start in their profession and to get their names placed upon the panel would give them an opportunity which they did not at present possess. Lord Midleton, however, voiced the widely-felt fear that the general extension of contract practice would make intolerable demands on the medical profession.

The question of remuneration remained in abeyance, and only just before the Act came into force on July 15th, 1912, appeared Sir William Plender's much delayed report on medical remuneration in certain selected areas, from which it appeared that the average annual gross income derived from patients attended under contract amounted only to 4*s*. 2*d*. per head of the population, and this report naturally did not help the British Medical

Association on the eve of its meeting at Liverpool, for the findings of the report were misunderstood and unfairly used by the political press. The Liverpool meeting continued to adhere to demands which the Government stated could not be conceded, and alternative plans were developed for a capable public medical service acceptable to medical men and beneficial to the public who, as THE LANCET reiterated, must not feel that they had been left in the lurch by the medical profession. These plans never materialised. Without admission of reconciliation either to the principles or to the working of the Act, active opposition to it gradually diminished, the Commissioners taking up an attitude of sweet reasonableness which proved disarming. The Special Commissioner of THE LANCET, who visited different centres during 1913 and 1914, found little hostility to the principles of the Act, although its administration was open to criticism in many respects. He was impressed with the enormous good which the fight had done in bringing together the members of the medical profession as never before. The great majority of practitioners were satisfied with the financial result and resentment was dying away. This was the situation on which the war intervened, and the story cannot be taken further with any advantage inasmuch as the position may be altered in the future.

INQUIRIES INTO PUBLIC MATTERS.

Of the last Commission instituted by James Wakley (see p. 723), who was strict in using this title for the inquiries which he set on foot, two of the most important were undertaken by Mr. Adolphe Smith, whose reports on a large range of subjects and over many parts of the world have formed for many years instructive reading to the medical profession and also to a much wider public, while reforms have followed frequently on the indicated lines, his help and that of THE LANCET being acknowledged. It is desired here to record briefly some of the work which he has undertaken for us. His report on the spread of disease through laundries revealed a common danger, and the detection that table napkins from a St. James's-street club were being dried in a Peckham garret over the bed of a small-pox patient was a telling episode in his account. The report on the contamination of uniforms led to investigations being made at the Army Clothing Depôt, questions in the House of Commons, and immediate disappearance of a scandal. Mr. Smith made personal visits to cholera centres in Europe at different times, it being necessary that our population should know that this country was not without its risks and that forearming was only prudent. From 1892 to 1894 he followed the cholera from town to town, throughout Europe from Calais to Constantinople. At the same time the few cases of cholera which occurred in England were not neglected, and we published the results of special inquiries at Hull and Grimsby. A curious anomaly in our local government was then discovered, for while the State incurred all necessary expenses to obtain information about the rare English cases, not a penny could be spent to investigate the widespread epidemics prevailing on the other side of the channel and only a few miles away. Therefore our Commissioner dealt in detail with the cholera in Paris, Brussels, Antwerp, produced spotted maps of the ports in most constant communication with England such as Calais, Boulogne, Dunkirk and, above all, Havre, where the epidemic was second in severity to Hamburg. But the most interesting cholera map was that of Hamburg itself. Not only was the case-rate and death-rate given for every district, but the nature of the subsoil and the average income of the inhabitants were given. The articles showed the progress of epidemiology since cholera was dealt with in detail some 60 years before (see p. 709).

Mr. Smith visited at different times Continental centres, and many American cities, reporting on their sanitary management, or on the particular epidemic crises which had brought him on the scene. Two investigations on the spot into the condition at the Chicago stockyards were made by him, the first in 1895 and the second, and more favourable, four years later. The revelations caused a *furore*, they were copied into the European press, and were made still more public by a novel, "The Jungle," in the writing of which the author, Mr. Upton Sinclair, acknowledged his obligations to our Commissioner. As a sequel Mr. Smith made a tour of famous abattoirs and dealt with the slaughter-house conditions at the different centres.

Two other out of many investigations initiated by the paper and carried out by Mr. Smith should be mentioned. The first concerned tailors in the East End of London and led to the nomination of a special commission of inquiry by the House of Lords. The original scope of inquiry had been confined to the circumstances surrounding a colony of Polish Jews, but the commission of the House of Lords extended the investigation, and Mr. Smith visited 150 sweating-dens in the provinces, the result being the publication of five large blue books and the institution of many changes for the better. A second valuable piece of work had its outcome in a series of articles on the free feeding of school-children in different countries. The information was particularly needed by school managers in this country, who were sorely perplexed by inability to meet the case of the half-starved scholar, and the articles were employed as evidence in the House of Commons during the debates which culminated in the measure for the Provision of Meals.

Following on the series of articles published under the heading of "The Battle of the Clubs" (see p. 755) came a set of inquiries into medical organisation, in the course of which Mr. Smith went thoroughly into all sides of contract practice at home and abroad, and was able to make suggestions which have since borne fruit. His articles, based on personal and local investigations, with the common heading of "The Organisation of the Medical Profession," were spread over the critical years, and in them he showed how well organised for mutual defence the medical profession was in Germany, France, and Belgium. At an international congress on Medical Deontology, held in Paris in 1900, all this work was discussed and full publicity given in our columns to the debates, while the Society of the International Medical Press was started.

THE WAR.

A group of medical men had a curious indication, in the fateful week preceding the outburst of hostilities, that those who continued to say that such a war as was threatened was unthinkable, and that some way would still be found to avoid it, were too optimistic. The Congress of American Surgeons was being held in London at the close of July, and from its deliberations there suddenly faded away some well-known German visitors.

With the outburst of hostilities we suffered the dislocation of business that was common to the country, and with the prolongation of the struggle we were put to the same shifts. No purpose would be served by dwelling on the various awkward positions brought about by loss of staff, shortage of paper, rise of prices, and restriction of publication, but concerning the last it should be said that nothing but a favourable memory remains in respect of the treatment that we received. We were able to keep our readers posted in all matters where the dissemination of the information was likely to be valuable to the medical profession, military or lay—and it will be remembered that more than half the civilian profession was required to serve in one capacity or another. The call by the forces on the ranks of medicine became so insistent that the needs of the population had to be kept before men's minds, and the contents of the paper, apart from the medical and surgical contributions and communiqués, were much occupied with all the questions arising out of the attempt to reconcile the two claims. The war also gave impetus to the full permeation of the ranks of medicine by medical women. The surgical unit at Endell-street removed official doubt that women could administer as well as operate, and paved the way for full representation of women in public capacities. The development of the movement which has resulted in their wide recognition can be read in our columns throughout a series of years, but in its earlier stages those responsible for the conduct of the paper were clearly much divided in opinion. It is long since any such division has existed, and to-day one of our most valuable and trusted lieutenants is a woman, and our staff is regularly recruited from qualified women.

The Medical History of the War, which is on its way to completion, makes any attempt to summarise the contributions to these columns quite unnecessary, and the time is too near at hand to hazard an estimate of their permanent value trustworthy. We published what we thought to be of the greatest use to our readers, and say no more of that side of our work save to draw attention to the prominent way in which the subject of nutrition came in for notice at the time, to establish itself since as a field for research of supreme importance.

Experiments in Nutrition.

Many circumstances combined to make the medical lessons of the War less substantial than was to be expected from the amount of skilled medical and surgical experience at the disposal of the nation. Only the science of nutrition blossomed as never before. The test-tube and calorimeter in the hands of the research worker were transmuted into world-wide experiments in national nutrition in which applied physiology had effective share. The publication in our columns early in 1915 of the Eltzbacher report on the Food Supply of the German People opened many eyes which had hitherto been blind to the possibility of rationing at home. "We can come through," said this report, "and the plan to starve us will founder on the voluntary coöperation of millions." The coöperation included a census of food animals and a restraint of the "senseless luxury" of eating bread and butter between meals. It was not much later that the U boats and Lord Devonport produced a similar concentration on food problems among thinking people in this country, and Sir W. Henry Thompson surveyed the food-supply of Great Britain and deduced the available daily ration. It was in The Lancet that Dr. Harry Campbell's articles on Food Economics saw the light, in which he showed with much spirit that the purchase of a picture or a Pekinese pup was not national extravagance in the same way as feeding pigs on whole-milk. It was in The Lancet, too, that an inquiry appeared into the unrestricted diet of a brain worker, the diet being no less than that of the chairman of the Royal Societies Committtee, whose appetite had evoked a playful reproach from Sir William Osler. Dr. Waller's justification was complete, for his daily average worked out at barely 2250 calories, the lowness of which surprised both himself and other physiologists. Indications of the many directions in which the effects of restriction showed themselves appeared in our columns: the disappearance of migraine, a reduction in the frequency of diabetes and of eclampsia on the credit side; an increase of tuberculosis, most startling in institutions, of rickets, of listlessness and inertia on the debit side; contrasted with the admirable health of the men living in trenches under conditions of cold, wet, strain, and anxiety, but fed like fighting cocks, the significance of food accessories gradually became apparent; the skins of potatoes and the juice of swedes came into great repute, and the straitened circumstances in Central Europe, which continued after the War, gave opportunity for the application of the new knowledge to the relief of deficiency diseases in Vienna and elsewhere. The inadequacy of our present knowledge of many important aspects of nutrition moved Prof. E. H. Starling, as scientific adviser to the Ministry of Food, when this Ministry came to an end, to plead for the creation of a permanent Board of Human and Animal Nutrition, for which he found The Lancet a ready supporter. Such a Board has now materialised, namely, the Food Investigation Board of the Department of Scientific and Industrial Research. The scope is indicated by a recent report on the Bacteriology of Condensed Milk, which was published in THE LANCET while these pages were being passed for press.

THE BELGIAN DOCTORS' AND PHARMACISTS' RELIEF FUND.

With the first inrush of refugees from invaded Belgium we got at this office a view of the terrible position in which doctors and pharmacists in that country were involved. Not only were their practices hopelessly disintegrated, but their premises were invaded and their stores commandeered, while here and there terrible tragedies were reported, the occurrence of which in some cases was later proved to be absolutely true. The Editor of THE LANCET convened a meeting of doctors to organise relief for the Belgian doctors and pharmacists, both those remaining in Belgium and those who had become refugees in this country. A representative gathering assembled in the offices of the British Medical Association, and a General Committee was immediately formed, including the President of the General Medical Council, the Presidents or representatives of the Royal Corporations, and of the medical faculties of the universities. Officers of the British Medical Association, of the Pharmaceutical Societies, and of the National Insurance Commission immediately joined, and from the beginning the British Medical Association gave every assistance to the movement through its large organisation. Sir Rickman Godlee became chairman of an Executive Committee which included the following :—

Sir Thomas Barlow, President of the Royal College of Physicians of London ; Sir W. Watson Cheyne, President of the Royal College of Surgeons of England ; the late Mr. Meredith Townsend, Master of the Society of Apothecaries ; the late Sir Alfred Pearce Gould, Acting Vice-Chancellor of the University of London ; Sir Frederick Taylor, President of the Royal Society of Medicine ; Dr. Herbert Spencer, Obstetric Physician to University College Hospital, London ; the late Sir Frederic Eve, Consulting Surgeon to the London Hospital ; Sir Jenner Verrall, then Chairman of Representative Meetings of the British Medical Association ; the late Dr. F. M. Sandwith, Gresham Professor of Medicine ; Mr. E. T. Neathercoat, President of the Pharmaceutical Society of Great Britain ; Dr. Alfred Cox, Medical Secretary of the British Medical Association ; Sir Dawson Williams, Editor of the *British Medical Journal ;* Mr. W. J. Uglow Woolcock, Secretary and Registrar of the Pharmaceutical Society. Dr. H. A. Des Vœux was appointed Honorary Treasurer, and the Editor of THE LANCET Honorary Secretary.

The work before the Committee was obviously twofold. It was necessary to provide assistance for the members of the medical and pharmaceutical professions and their families who were refugees among us—and this was in many instances a matter of real urgency—while with regard to the victims of the German occupation, it was at first impossible to do more than despatch certain packets of medical material with which the misery created by the wholesale destruction of laboratories and pharmacies might be to some extent relieved. A start was made in this direction immediately, and packets were sent regularly to Belgium as soon as it was known that through the good offices of American and Spanish representatives the packets would be allowed to reach their destinations without interference. Along these two lines a comprehensive scheme was organised and an appeal was made to all medical men. Subscriptions were opened in Scotland and Ireland and a substantial sum of money was being received when late in 1914 Prof. C. Jacobs, of the University of Brussels, described in our columns and those of the *British Medical Journal* from personal knowledge the distress to which the allied professions had been reduced in Belgium. In the provinces of Brabant, Limburg, Liége, Namur, Hainault, and Luxemburg, our confrères were suffering terribly. At least a thousand medical men and three hundred pharmacists were known to be absolutely poverty-stricken, and others had been taken as hostages, their dependents remaining deprived of everything.

This deplorable message aroused widespread feeling, and the Executive Committee obtained early the invaluable sympathy of the American Ambassador in London. It became clear that it would be possible to transmit medical material to Belgian doctors and pharmacists upon some regular plan, and possibly to arrange for the sending of money. The first subscriptions were used as grants to relieve immediate distress in suitable cases, the responsibility for these grants being undertaken by the Editor and Dr. Des Vœux, the treasurer of the Fund. Every day for many weeks medical refugees belonging to one or other profession, or some member of their families, were interviewed by the Editor or Dr. Des Vœux, often by both. A list was made in which the positions were roughly categorised into those where assistance would clearly be required for a long period and those where, if the emergency could be met, the finding of employment was possible. Dr. Des Vœux organised a collection and distribution of clothes, and a large number of suits for men, dresses for women, overcoats and woollen and linen goods were received and distributed. At many times during the whole of 1915 the number actually dependent upon gratuities was large, but gradually the situation was relieved in different directions. The General Medical Council sanctioned the practice of qualified Belgian practitioners in England, when the registration fees were paid by the Fund, and an appreciable number of men were placed in a position to earn their livings. Others were enabled to join their own fighting forces on the Western Front, while some obtained employment through their own exertions and the ministration of friends. A number of pharmacists took advantage of classes arranged by the Pharmaceutical Society of Great Britain for the instruction in English methods of dispensing and reading and translation of English prescriptions. A gratuitous class was conducted daily by Prof. H. G. Greenish and Mr. H. S. Phillips, and the instruction enabled the members to find employment.

By the beginning of 1916 we received the welcome information from Belgium that the Fund had been of real assistance to many Belgian doctors and pharmacists, a moving message expressing "the gratefulness of their little children." And at the beginning of 1916 the first cash account showed that over £18,000 had been received. By the middle of 1916 the Fund, through the agency of Mr. Herbert Hoover and the International Commission for Relief in Belgium, was able to get into close connexion with a society, the Aide et Protection aux Médecins et Pharmaciens Belges Sinistrés, sitting in Brussels, and from that time forward £200 was sent each week for a considerable period. The Belgian Committee was under the presidency of Dr. V. Péchère, with Dr. Laruelle, and Monsieur A. Delacre as secretaries, and Dr. H. Coppez as treasurer. The officers of the Belgian Association soon began to transmit to the British Fund *comptes rendus* of their proceedings, and it became obvious that the avowed object of the Fund would be largely achieved if money could be sent regularly to Belgium at the rate at which it was then being transmitted. During 1915, 1916, 1917, and 1918 accordingly money was sent in instalments to Brussels at the rate of at first £800 per month. Towards the end of this period the Fund began to run short of money. In July, 1918, a further appeal was organised, with the result that it was possible to maintain the subsidies until the end of the War, and to make a final distribution of £211 balance. Some generous help from America reached the Fund in the last critical stages. £25,790 were received, and £1143 were earned by investment of capital from time to time. £25,863 were given as relief, including a small sum as unreturned loans. Drugs and clothes cost £600 and printing £200. The postage was largely defrayed by THE LANCET.

At the close of 1919 Dr. Péchère paid a visit to this country in order that he might give to supporters of the Fund the thanks of those who had been helped.

THE FRENCH SUPPLEMENT TO THE LANCET.

Immediately after the war we issued a French Supplement which at monthly intervals appeared for four years. The supplements were intended to enable British doctors to understand the work of their French colleagues, and were sent to us under the editorial direction of Dr. Charles Achard, professor of pathology and therapeutics in the University of Paris, and Major Charles Flandin, D.S.O., Chef de Clinique à la Faculté de Paris. The supplements were shaped to include a general view of some big medical subject, and an original article dealing with a particular question. They had a good reception, and it is intended to continue them when mechanical difficulties in carrying out reciprocity are a little easier, for it was a particular pleasure to enter again into close communication with France, and show in a practical if limited way that medicine does not acknowledge racial boundaries.

THE MINISTRY OF HEALTH.

The Ministry of Health came into being on June 3rd, 1919, the arguments for its foundation having been told and retold till they can require no repetition. The Ministry was no new thing; in true British spirit it was a survival of what was best in many existing activities. Under the new Ministry medical work was coördinated with the work of other Departments, its activities being enlarged and redirected in object, and, in particular, arranged at one centre, thus obviating the waste, embarrassment, and disappointment associated with multifarious different and overlapping organisations. There were transferred to the Ministry the powers and duties in respect of public health of the Local Government Board and the Insurance Commissioners, and those of the Board of Education with respect to the health of expectant and nursing mothers, and children below school age. The medical inspection and treatment of children and young persons under the Education (Administrative Provisions) Act, 1907, as recently extended and amended, also fell under the scope of the Ministry, as well as the powers of the Privy Council under the Midwives Act, and those exercised by the Home Secretary under Part 1 of the Children Act, 1908.

How the Ministry has discharged its official work in respect of the general health of the people under these references, which, wide as they are, do not include its whole responsibilities, can to some extent be gauged by the regular publication in THE LANCET of the medical reports or abstracts of them, and of the various official communiqués. The medical work within the Ministry was at an early stage organised under six main headings, and reports have appeared in our columns dealing with the action of the Ministry in connexion with general health and epidemiology, maternity and child welfare, tuberculosis and venereal disease, food-supplies, sanitary administration, general practitioner services, and international health.

The full value of the scheme of medical treatment cannot be pursued unless the medical practitioner, instead of being an agent for the treatment of obvious disease, recognises and handles it in its early stages, and becomes also a missionary of personal hygiene in its preventive aspect. This is the view of Sir George Newman, the Chief Medical Officer of the Ministry; it has always found expression in our columns, and it underlies the Interim Report of the Consultative Council on Medical and Allied Services.

In many aspects and on many occasions the great question of the pecuniary support of the hospitals became a critical one under the development of the Ministry of Health and the National Insurance Acts, and it has been a source of satisfaction to find that the steady support of the voluntary system, which was so marked a feature of our youth, could be maintained not through any reluctance to a change of mind, but because the advantages of the system invariably out-weighed any to be derived from its abolition.

S. A. VASEY.

In conclusion we must record the loss that we experienced by the death of Mr. S. A. Vasey (Fig. 41).

Samuel Archibald Vasey, who succeeded Heaton (see p. 748) at THE LANCET Laboratory, died at the end of 1920, aged 58. For 28 years he had conducted inquiries of all sorts at THE LANCET, and little important work in chemistry or physics having a bearing upon health and happiness escaped his notice. The terms of reference in the laboratory were wide, and Vasey stretched them, as will be seen by a few instances of his catholic labour. In many text-books his findings have been recorded with approval, and into more than one Act of Parliament his recommendations have found their way practically unchanged. He was the author of a probing series of articles on abortifacient quackery, and the part author with Sims Woodhead of a useful report on the standardisation of disinfectants.

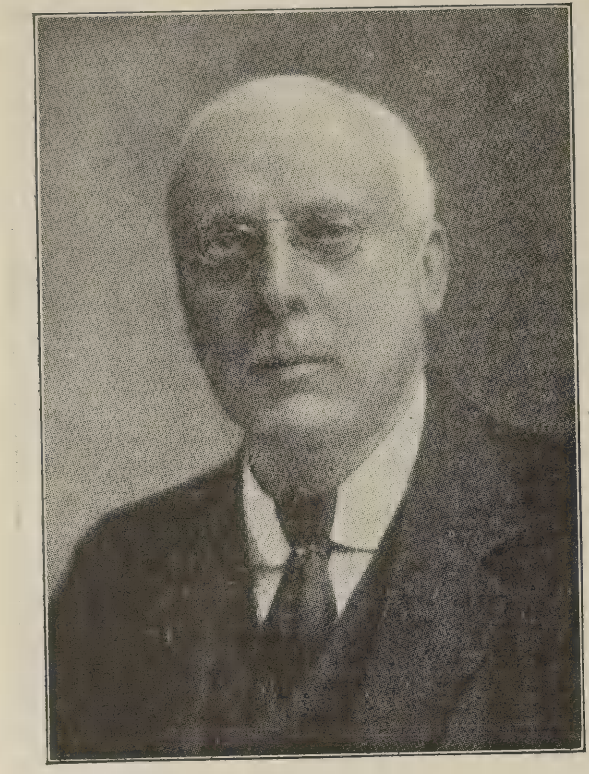

FIG. 41.—S. A. VASEY.

He made a thorough investigation into the physics of gas-lighting and into the whole subject of heating by means of gas, and in the course of the latter work he supplied manufacturers of gas stoves with much information which they required for the regulation of mechanism and the securing of economical results. He brought an intimate knowledge of air impurity, acquired in various researches, to bear upon the whole subject of coal-smoke abatement. He was the author of exhaustive inquiries into the two forms of alcohol sanctioned by the British Pharmacopœia, brandy, sherry, and into claret, the most frequent wine for ordinary drinking. He never exhausted his subjects with chemical résumés, and here he took full opportunity during his investigations at the vineyards to acquire information about soil, weather, and traditional routine, giving a broad character to the history of the three fluids. Others of his inquiries, conducted far afield, were those into the chemistry and natural history of continental waters, such as Apollinaris and Hunyadi János, and to the stock-breeding areas in the Argentine belonging to the Liebig Company.

The medical profession were further informed by his analyses on such various topics, small but of wide-ranging importance, as the nicotine contents of tobacco, with reference to pipe-, cigar-, and cigarette-smoking; the food value of oysters and the risks in their breeding and supply; and the danger which lay in the employment of certain flannelettes. His application of science to the things of daily life became a habit—part of his mental make-up. This was notably the case in regard to food, and constantly found expression in our columns. A luncheon to him was so many calories, with perhaps too low a protein factor and a deficiency in fat-soluble A. Atoms, ions, and sols in his mind kept familiar company with food, drink, clothes, and the raw materials of industry.

We have had good friends, and good friends have regularly taken their places, but Vasey, the man of science, who could bring his academic and practical learning to bear on the commonest problems of life in relation to medicine in its broadest sense, has been irreplaceable.

ENVOI.

We have left undone things which we ought to have done, and some things which we have done have not fulfilled their objects. But we have spared no pains to maintain the status of medicine and to assist in the progress of medical science by the diffusion of its hopes, its tenets, and its results. For the recognition of these efforts we thank our readers.

THERMOGENE

TRADE MARK REGD.

CURATIVE WADDING

The use of counter-irritants is often limited in effect through the evanescence of the agent employed. The value is proportionately increased if the improved circulation of the blood in the affected part is long sustained.

Commonly, counter-irritation is succeeded by early reaction and the good effects are quickly dissipated by conduction and radiation.

Thermogene has the merit of overcoming all these difficulties. The counter-irritation may, by using Thermogene, be definitely prolonged and the surface heat almost entirely conserved.

The value of Thermogene as a reliever of pain, especially those forms associated with catarrh or inflammation of the respiratory passages or rheumatism of muscles or joints is well known to all who have used it. Moreover, it is always ready, is cleanly in application, and calls for no skill in use.

Thermogene is indicated in :—
Rheumatism, Neuralgia, Laryngitis, Stiff Neck, Lumbago,
Influenza, Neuritis, Sciatica, Synovitis, Arthritis, etc.

Introductory Addresses

PROBLEM OF SUCCESS FOR MEDICAL WOMEN.

Delivered at the London School of Medicine for Women on Oct. 1st, 1923,

By Sir HUMPHRY ROLLESTON, K.C.B.,
PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON.

[Sir Humphry Rolleston began his address by referring to the rapid progress made by women in the medical profession since the London School of Medicine for Women was opened in 1874, and went on to examine the difficult question of the factors which make for professional success with women doctors:—]

Since the time of Darwin it has been recognised, though not without protest (Karl Pearson), that variability, both in body and mind, is more frequent in the male than in the female sex, so that genius, originality, and initiative, as well as idiocy and crime, are more frequent in men than in women, who tend to preserve a more equable level; men have a greater aptitude for abstract problems, women for concrete subjects. Now taking into account only the factor of the vastly greater number of men than of women in the medical profession, and remembering the relatively small percentage of men of outstanding ability that it has produced, it is surely not surprising that women doctors have so far not numbered among them any to rival Lister, R. Koch, Osler, and Horsley. Further, the number of women who give up the pursuit of medicine, before or after qualifying, is probably relatively much greater than in the case of men, mainly because marriage seriously depletes the ranks of women doctors; further, it is widely held, though statistical proof of this would be difficult, that it is the ablest who thus fall by the way. It has been stated (L. Martindale) that 30 per cent. of all women doctors marry either before or after qualification, and, though what proportion of these retire from active practice is not known, it commonly must act as a handicap to women, whereas it is of necessity a stimulus to male practitioners. But to return to the sex-incidence of genius—that extreme natural variation—there is, as just pointed out, the additional factor of greater uniformity among the female sex to reduce the probability of the occurrence of phenomenal ability among them.

Sex Differentiation.

Study of the world's history has convinced Mathilde and Mathias Vaerting, whose remarkable book "The Dominant Sex: A Study in the Sociology of Sex Differentiation," has recently been translated into English, that the relationships of the sexes as regards dominance vary in a manner resembling the swing of a pendulum; in a few instances women have had the upper hand, as in ancient Egypt, Sparta, the Garos in India, and the Iroquois; in the vast majority of nations, of course, men have been predominant, and very exceptionally the rights of the sexes have been nearly equal, as in the State of Wyoming; during the phase of male predominance there has been a conscious or unconscious tendency to obliterate the evidence of former feminine dominance, or, expressed more generally and at the same time more forcibly by the Vaertings, "history is perennially falsified by the prepotent ideology of the dominant sex." In nations under feminine dominance the woman supported the family and went out to work while the man was the housekeeper and domestic drudge; such division of labour is not ascribed to biological or physiological differences, but depends on the dominance of sex; in fact, the women of a nation in which the female sex is dominant become from the attendant circumstances physically fitter than the men. The notion that inborn physiological differences between men and women determine the usual superiority of the male is argued to be due to confusion between cause and effect.

The force of tradition and the suggestion that man is the dominant partner is not easy to estimate accurately in regard to medicine; auto-suggestion may well be of some importance; but that a woman doctor would consciously abstain from research and striking out a new line because it is commonly regarded as peculiarly a man's sphere seems improbable. Nevertheless the tradition of maternal ancestors (feminine heredity) and its social influence on the early life of a generation that has witnessed the wide opening of careers to women cannot be neutralised at once, and its effects may persist for some time. That women as a class are inherently more law-abiding, more subject to what they regard as conventional, and more conservative might reasonably be interpreted as the outcome of long-continued subordination to men's ascendancy. More than a hundred years ago Sydney Smith laughed at the idea that there was any inborn difference of intellectual capacity between men and women, and argued that the conditions of education were entirely responsible for the existing differences. Further, in the report of the Board of Education's Consultative Committee on the Differentiation of the Curricula for Boys and Girls respectively in Secondary Schools (1923) the opinion is expressed that there is little difference in intellectual capacity between the two sexes, though there are noticeable divergencies in emotional response as indicated by the degree of interest evinced for various studies, and that on the whole the apparent differences revealed up to the present by psychological inquiry would not seem to justify any serious differentiation in the actual curriculum.

Effects of Tradition and Heredity.

It is obviously important and equally difficult to apportion accurately the influence of environment, tradition, and suggestion on the one hand, and hereditary and inborn tendencies on the other hand. The circumstances of women doctors and students of medicine, though infinitely better than sixty years ago when the struggle for any opportunities at all was in progress, are even now not so good as those of men; for example, the hospital facilities and appointments open to them are still restricted as compared with those of men. On the other hand, it must be remembered that some of the best work done by men has been accomplished in the most unpromising surroundings; and it has been truly said "genius does what it must, talent what it can."

Though much less than in the past, the sexes still lead different lives; girls are more prone than boys to follow an indoor and confined routine, and so to impair or retard a robust physical development; and thus sexual peculiarities are accentuated. The physiological disabilities arising out of sex must be taken into very serious account as a weighty factor in determining women's chances of a successful struggle in intellectual work and practice of the profession of medicine. In 50 per cent. or more of women the monthly rhythm is a distinct handicap, and its manifestations are prone to be aggravated by a sedentary life and other factors prejudicial to a vigorous state of health, factors often inseparable from the life of a hard-worked doctor in town or institutional practice. For the greater part of their active life a large number of women are liable to recurrent interruptions in their state of efficiency, and are thus at a grave disadvantage as compared with their male competitors; among men migraine, which might be regarded as comparable in its periodicity and effects, is relatively so rare that it rather tends to emphasise the reality of the women's burden.

[Sir Humphry Rolleston concluded this section of his address by supporting the view that women have in a more developed degree than men the power of arriving at the correct solution of problems *per saltum*, and went on to estimate the ability of women medical students by their examinational distinction:—]

It may be interesting to compare the percentage of qualifications among men and women entering the medical profession. Sir James Paget's well-known analysis in 1869 showed that of 1000 medical students at St. Bartholomew's Hospital, 776, or 77·6 per cent., actually qualified; of Sir Squire Sprigge's smaller series of 250 students in the early 'eighties from St. George's Hospital, 187, or 75 per cent., qualified. Miss L. M. Brooks, your warden, has kindly analysed for me the results of 700 students entering the London School of Medicine for Women between October, 1894, and July, 1914; of this number 593, or 84·7 per cent., completed the qualification for which they entered; this proportion is much the same as that (about 85 per cent.) arrived at by the General Medical Council in 1907, and that (87 per cent.) of the students entering St. Thomas's Hospital in the years 1890–99 (Edred Corner). As far, therefore, as these few figures go, women students have held their own. It is satisfactory to learn that the death-rate during pupillage, which in Sir James Paget's series was 4 per cent., was halved in Sprigge's and Corner's series, and was little more than 1 per cent. (8 in 700) among the students of this school.

Possible Danger of Early Success.

Though a high place in the class list provides a good start and is prima facie ground for anticipating success in after life, it is, of course, no guarantee for women students any more than it is for men. Although many prize-winners continue to be front-rankers, early success is not without its possible danger; it may breed conceit and slacken effort, so that the highly placed may become extinguished by their distinction. An early failure is sometimes a blessing, however much it may be disguised. Another consolation for those who fail to find favour with examiners is that some students develop late, and so at first do not compete on equal terms with their more brilliant rivals, though eventually they surpass them in the race of life. To the make-up of a capable medical practitioner professional knowledge is not the only property necessary; practical efficiency, presence of mind, wise discretion, sympathy, and a thorough understanding of human nature are other essentials. Academic success may be obtained by mental ability, industry, and a temperamental power of making the best of knowledge thus acquired. Book knowledge may therefore go further in the examination test than in the daily round of practical life.

Women are, on the average, better students than their brethren; they work harder and take more pains, being whole-mindedly concentrated on the subject in hand. So much so indeed that many of them find it difficult to throw off their work for a time, and therefore tend to get stale and mentally dyspeptic. The power of detachment, by which mental concentration can be transferred from one thought-tight compartment to another, is of infinite value.

Relaxations.

The importance of cultivating a hobby, distraction, or avocation to balance and correct the more urgent claims of professional studies is a commonplace, yet like many dictates of common sense it is often ignored. Literature, music, art, and athletics are not only part of a liberal and humane education, but invaluable as a means of refreshment and of re-creating energy for the business of life. Just as there are burly athletes who never study, so are there pale students who go to the other extreme and thereby endanger their future by undermining both their mental and their physical efficiency. As a class women students are more prone than their brothers to over-devotion and thus to narrow their intellectual outlook and their chest development; to them, therefore, it is not so necessary to insist on the obvious need for industry, what Sir William Osler in his charming "Æquanimitas" called "the Master-word in Medicine," as to remind them that the best student combines mental and physical prowess, and thus realises the ideal of the *mens sana in corpore sano*. It has not uncommonly been urged in introductory addresses such as this that hard work alone seldom leads to a breakdown and that worry or some extraneous factor is the real cause; this is a rather over-stated, though no doubt admirably meant, exhortation, and is perhaps more applicable to those whose life's work is free from the menace of the examination bogey than to the students, especially women, whose mental vision is too often focused anxiously in that direction. It may be partially true when hard work can be secured from worry, but even then the interference with physical health must be taken into consideration. Much, therefore, turns on how the work is done, wisely or otherwise, and on the physical and mental make-up, so to speak, of the individual. Women students especially should remember that there are occasions when the willing spirit should be mindful of the weakness of the flesh, and that as a class they are more liable to mental breakdown from overwork. There are disadvantages in reading too much.

Rarity of True Genius.

[The lecturer, having reminded the audience of the differences between bookish learning and practical wisdom continued:—]

In the opinion of experienced teachers, such as Prof. W. D. Halliburton, while the average female student is on the whole superior to the average male student, possibly because the women who take up science are usually keener and feel a call to do so, the best women students are not so able as the best men students. This estimate indeed is on the same lines as the generally accepted view that true genius is even rarer in women than in men. Now whether this is due to inherent sex peculiarities or is the result of long-continued dominance of the male sex or to both these factors is an academic though interesting question.

It has been stated that each individual contains the potential elements of both sexes, one being of course dominant, though varying in individuals, probably in correspondence with the influence of the hormones from the endocrine glands, especially the gonads. According to Otto Weiniger and W. L. George, "there are no men, there are no women, but only sexual majorities." Although this view may not now be accepted and the endocrine glands are now considered to influence emotional rather than intellectual activities, there are most remarkable individual differences among members of the same sex, and everyone has known feminine men and virile women. As all kinds make a world, provision must be made for all, and it is among the masculine-minded women that variability tending to the production of genius or of special ability may be anticipated. Perhaps too much stress has been laid on the small number of women doctors who have made epoch-making advances and on the view (correct as it may be) that as a rule women students are less original in mind, less inclined to initiate new lines of thought, and are more successful as conscientious followers than as independent leaders in research. There have been exceptions in the past to any such rule, there are more in the present, and in the future there can be little doubt that women workers will take an increasingly larger part in research, whether independently or under the inspiration of a great teacher. The establishment at the Royal Free Hospital for a whole-time professor (Dr. Louise McIlroy) of obstetrics and gynæcology with a clinical unit is a notable step in advance and offers opportunities for realisation of this belief.

The Measures of Success.

But after all, success in our profession is not solely measured by ability for research and the discovery of the truth, any more than by the accident of popular approval that brings with it wealth and a prominent place in the limelight. There is the satisfaction of honest work quietly carried out with the knowledge that duty, hard and unremunerative though it may be, has been done. The truest success in the art of healing does not, as it does in pure science, depend solely on intellectual pre-eminence; there are the properties of the heart as well as those of the brain, perhaps best expressed in the familiar text—

> "Though I have the gift of prophecy (prognosis), and understand all mysteries (diagnosis), and all knowledge; and though I have all faith, so that I could remove mountains (confidence and operative skill), and have not charity, I am nothing" (I. Corinth., xiii., 2).

In the keen pursuit of scientific diagnosis, which is a purely intellectual process without room for the emotions or sympathy, there is a risk that the patient may be regarded and treated as a machine out of order, and thus the plight and feelings of a suffering fellow creature may be forgotten. A doctor should add to the abilities of an engineer and chemical expert of the human body some of the attributes of the broad-minded Churchman. Sympathy demands imagination, and both of these specially feminine properties should be preserved as valuable assets in our profession, and not transformed into callousness by contact with the naked and often repulsive aspects of a doctor's life. Imagination should supply an insight into the mind of the patient and an understanding of the fears and anxieties of those who come to be cured. Without this conception of the patient's point of view the student may think only of the diagnostic problem and forget the human aspects. The influence of cheerfulness and of reasonable optimism on the sick should be ever borne in mind; yet this may easily be forgotten in the presence of dour reserve even amounting to bad manners, really due to the patient's worries and self-consciousness. With a cheerful manner should be combined a degree of concentration sufficient to convince the patient that his condition is receiving serious attention; it is hardly necessary to carry this so far as to give the impression to every patient that he is the only person who counts in this world. Tact and self-oblivion, essentially feminine properties, are of great value in medical practice, and should therefore be preserved by medical women and not, as perhaps is sometimes the case, repressed or discarded by the more vigorously minded. As scope for the emotions and human interest are important factors in rendering work congenial to women, this would appear to be an additional reason why most women are more suited for practice than for pure laboratory research.

Though this address is headed "The Problem of Success for Medical Women," at this comparatively early stage of women's activity in the medical profession it is not wise, and indeed is hardly possible to say the last word on this subject. That medical women have succeeded in the face of great difficulties is shown by recent history, and now that circumstances have been so vastly improved by their efforts the road has been opened to their successors. The way, no doubt, is long and beset by difficulties; patience, perseverance, and wisdom are necessary, but there is encouraging evidence that by these means women may look forward to a just meed of success.

THE PROPER UTILISATION OF THE SENSES.

Delivered at the Opening of the Session of King's College Hospital Medical School on Oct. 3rd, 1923.

By H. J. WARING, M.S. Lond., F.R.C.S. Eng.,
VICE-CHANCELLOR OF THE UNIVERSITY OF LONDON; VICE-PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

I intend to say a few words to you to-day on the way in which we, as students of medicine, form conclusions or come to decisions. I say purposely *as students* for all of us in one way or another are students of our great science and art, and it has occurred to me that it may be useful to you who are entering upon or are already entered upon your professional studies if I offer some remarks on the way in which, as it seems to me, we arrive at our conclusions in the practice of medicine and how we can best ensure that those conclusions shall be the correct ones.

Now, if our conclusions are to be sound, if they are to afford a satisfactory basis for action and treatment, it is obvious that they must in their turn be based upon accurate data. And so I must first of all lay stress upon the importance, the supreme importance, of the *proper*, that is the *intelligent*, use of the senses—of sight, of hearing, of the muscular sense, touch and smell and taste—in the practice of medicine. This is, of course, no new theme; it is, indeed, a very trite one, and some of you may very likely be disposed to say to yourselves, "All this we have heard before." That may be so. But sound doctrine does not lose its validity because it is not fresh and because it has often been taught before; we must not, I think, assume that it has been acted upon—there are some excellent rules about public health enunciated by Moses which I am afraid are not observed by a good many communities in Europe.

The Understanding Eye.

Now what do I mean by the *intelligent* use of the senses? I mean using with understanding those wonderful natural instruments with which we are provided, and which it is the especial business of a medical education to call into action, to stimulate, to train, and to educate. Take for instance *sight*, in many ways the most important of these senses. You will doubtless have learned that considered merely as an optical instrument the human eye is far from perfect, and any oculist could suggest divers ways in which it could be improved. The important thing, however, is not the mere instrument, it is the mind which is using it. The doctor's eye especially must be a "*seeing eye*," an eye which has not only the power to identify, but an eye which has been trained to look for things. It sees *actively*, it is *aware* of things. The camera and the microscope, though they are optically more efficient instruments, are, properly considered, only extensions of the eye, and the most detailed micro-photograph or skiagram will have no meaning, that is no significance, to an eye which has not been trained not only to identify—that is relatively easy—but to seek for objects, appearances, and signs with an understanding eye.

So, too, with the other organs of sense—the sense of hearing or of touch. The stethoscope reveals nothing except to a trained and discerning ear, and the finger of the physician and surgeon is itself an instrument so delicate and sensitive that I could not, if I wanted to, over-emphasise its service to him, and through him to the ascertainment of signs and symptoms and the causes of sickness and injury. Every physician and every surgeon can tell you of mistakes—some serious, some merely ludicrous—which have been made by young practitioners (and not always by the *young*) by failure to recognise or identify an outward and visible sign which was plain and unmistakable for one who would simply make use of his senses. Thus, how many of us at one time or other have mistaken a glass eye for a real one? On more than one occasion I have seen a student make a careful examination of an artificial eye and write a careful report thereon as to its optical capacities, without discovering that it was not real. Also students in the earlier stages of their career frequently mistake a normal physiological condition for a diseased one.

Some of you are now just entering upon your clinical work. You are looking forward, I have no doubt, to getting into the wards, and you are anxious, and rightly anxious, to get to grips with the more practical side of your work. But glad as you doubtless are to have finished, for the time, with your preliminary scientific studies, you would be making a mistake, and a serious mistake, if you regarded these merely as a regrettable necessity in your career—as something in which you pass examinations—and still more so if you were to cast them behind you as things of the past entirely. You have, in fact, already been learning the great lesson of observation ; your senses have been trained and educated to some extent. In your study of biology you have been searching for and *observing* the manifestations of life in their simplest form, and searching for the explanation of the processes of life. In your anatomy and physiology you have been *observing* and noting the structure and functions, the framework and the organs, the mechanism, physics, and chemistry of the human body, and all this important work, this group of sciences all converging upon the human body, is not only the foundation of your clinical studies, it is the preparation for the art of observation and reasoning which should accompany those studies.

The Example of Lister.

The importance of all this is exemplified in the life and teaching of Lister, who is very rightly regarded as the greatest ornament of your school and hospital, as he is one of the chiefest glories of English surgery. Why was Lister such a great force in the history of surgery ? And what was it that enabled him to revolutionise surgical practice throughout the world ? There are a good many answers to these questions, but if you read his life you cannot fail to be struck again and again by his constant habit of patient *observation*. There was nothing which he stressed more in his teaching than the value of the " faithful eyes." And he practised what he preached. He *saw* things which others either did not see, or if they saw they did not regard as significant. And note this : Lister was well grounded in the preliminary sciences, and he maintained his interest in them and made them his concern right through his life, in spite of the fact that he was a busy practising surgeon, and that, as I can assure you, the leisure of practising surgeons is extremely limited.

Notice this also, that it was Lister's interest in and knowledge of the basal sciences which enabled him to formulate his great principle of antiseptics. I speak of the principle, for the particular method is a matter of secondary importance. There is not at first blush a necessary or an obvious connexion between phenomena of yeast ferments and the employment of agents to prevent the admission of pathogenic organisms to a wound, but the connexion between these two is as well established as anything in the history of medicine. I feel sure, too, that the study of organic chemistry and biochemistry, physics and biophysics, is in the future destined to be very fruitful for medicine, and I hope it may fall to some of you to bear a part in the advancement of medical knowledge in this way.

But you may say, and quite properly, that we cannot all be Listers. Most of you will, no doubt, undertake general practice, and that is a high and an honourable calling. It is upon the general practitioner that in the main falls the duty of ministering to the needs of the mass of the population, and a good medical school will always aim at training and equipping good general practitioners. It would be wrong to suggest that the general practitioner does not make *his* contributions to the advancement of medicine ; that, as we know, is emphatically not the case, and many improvements in method and technique are due to busy practitioners working very often in isolation.

On the whole, however, the general practitioner is concerned less with the prosecution of research and the advancement of knowledge than with the early diagnosis and treatment of the varied ailments and diseases. Is there not, in this beneficent work, as great a need as in any branch of practice for the cultivation of continuous, accurate, and intelligent observation ? Most emphatically, yes ! Indeed, the conditions of general practice necessitate, I think, even greater use—accurate, intelligent use—of the organs of sense than in many other cases. The general practitioner must not only on occasion make quick and important decisions, based, of course, on the best readily available data, but they have also to be made under conditions of difficulty. He may be called out of bed in the night to undertake, unassisted, an emergency operation ; he may have to decide in a bad light, in circumstances of difficulty, the nature of a possibly infectious ailment ; or, perhaps, after a serious accident to make up his mind what should be done and how he is to set about doing it. The resources of a great hospital are not available to him ; he cannot verify his conclusions immediately by the X rays or by sending a smear or other material to the pathological department ; he has to act without consultation, without being able to avail himself of modern physical and chemical methods of diagnosis, and, as I have said, he must often act quickly. In such a case is it not obvious that the intelligent—the understanding—use of eye, and hearing, and touch and smell is of fundamental importance ?

Conflicting Evidence.

Now let us suppose that these faithful servants of ours, the senses, have done their work. They have obeyed your behest, and they have furnished you with their reports on the results of what can be seen and heard and felt and so on. In a great many cases their testimony will be so unanimous and corroborative that the task of forming a conclusion will be a comparatively easy one. Eye and ear and finger all tell the same story in the most significant way. Sometimes, indeed, the eye alone will suffice, and many a physician and surgeon has formed a provisional conclusion as soon as a patient has walked across the room.

The difficulties begin to arise when all the witnesses do not say the same thing—when they appear to contradict each other or when their reports do not agree in emphasis or assurance, even after further trial. They have done their task to the best of their ability—and that best may be an exceedingly helpful one—but the work of deciding is now matter for the mind ; that has now to balance, to sift, and reject. Observe that even the negative evidence of the senses can, *if it be accurate*, be of great use. By its use certain possibilities can be ruled out and the field of alternatives is by that much narrowed. The elementary rules of logic will hold good for some way—a thing cannot, for instance, both be and not be. But logic, you will find, certainly the logic of the schools, will not help you greatly. Few minds work by syllogism ; and I am fairly sure that very few medical minds do so. As logic and life are very different that is perhaps no bad thing.

After you have narrowed your field very drastically there may still remain several alternatives which are fundamentally opposed although superficially, and in some respects, the opposition is not obvious. How are you to proceed ? In a contest of evidence which witness will you believe ? Well, it may be that one witness will answer so clearly, so definitely, that you will be safe in placing reliance upon its testimony. It may be that on further inquiry other evidence may be forthcoming which will corroborate that testimony. But not infrequently you will find yourselves taking up with an hypothesis—you say to yourselves, " Let us suppose so-and-so " or " let us assume, provisionally, such and such." In that way you formulate an hypothesis which will account for some of the data. You do so and then test it with reference to the remainder. If it fails completely to satisfy these, then you know that it is inadequate and find another. That in its turn may not meet the case, and you may be driven to adopt and reject several until at last one is met with which will satisfy all the data. If it is the only hypothesis that does so you are then in a position to form your conclusion—you have, in fact, already done so—but it may happen that more than one hypothesis will occur to you, and that two may, though with differing degrees of certainty, harmonise and reconcile apparently conflicting data.

The mind is then working (and with experience is working with extreme rapidity) in selecting, rejecting, harmonising, and reconciling in order to find the solution to the problem which is to form the basis of action. This process, so subtle and delicate, is extremely difficult to define. I can picture it (but it is not a very satisfactory picture) as a kind of supersensitive organism shooting out innumerable fine tendrils which grope about as it were in the dark, searching for something tangible, and rejecting continuously until it is satisfied. And it is not always a conscious process. Often, indeed, it appears that a subconscious, or an intuitive agency, has been at work, and we make what appears to be a happy guess. Do not misunderstand me or do not be astonished at such a homely and unscientific word. I say "guess" because we cannot without difficulty retrace the path in our mental process which we have taken so rapidly and which has brought us out successfully. We seem to have blundered as it were upon it.

GUESSING.

It is not, of course, a guess any more than Archimedes "guessed" the answer to his problem and shouted "Eureka" in the bath, for the mind has been at work on it. And it is disciplined and trained mind, though it has, perhaps, seemed to play—at any rate it has not in many cases appeared to approach the question directly. Perhaps, some day, our psychologists may throw some more light upon the process—in the meantime I shall say "guess."

But obviously these delicate mental processes, whatever be the name you care to give to them, depend for their validity upon getting your facts right in the first instance. A small and seemingly insignificant difference in your initial data may prove of enormous consequence when it has turned the scale in forming the conclusion With practice and experience you will, of course, become apt to suspect that this or that detail has been overlooked—you will, so to speak, "look again" to see whether the facts have been correctly noted, and see if they do not accord with a probable hypothesis. That, however, will only come with experience, and with experience there will have come—there should have come—the habit of close observation, careful examination, and avoiding those mistakes on which so much depends.

Observe, make intelligent use of all your senses, and again observe! That is, I think, the first great lesson for us—and the rest shall be added unto us.

"PRACTICE."

Delivered at St. George's Hospital Medical School on Oct. 1st, 1923,

BY E. B. TURNER, F.R.C.S. ENG.,

DIRECT REPRESENTATIVE ON THE GENERAL MEDICAL COUNCIL.

GENTLEMEN,—A student of St. George's, I stand here to-day to greet those of you who have experience of this school on your return at the commencement of another academical year, and to welcome those of you who are making their first appearance to-day at the "Corner." I also wish to congratulate all of you both on your choice of a profession, and of the hospital and school in which you will complete your preparation for your future work.

Our profession, proved in peace, found itself in war. From the days before Galen and Hippocrates altruistic, self-sacrificing, truth-seeking, it has worked steadfastly towards the light. Whenever possible, discarding mere empiricism, it has based its advances on the sure foundation of scientific fact, and has attained its present position through the unselfish efforts of numberless workers and observers ever striving to raise the sister sciences of medicine and surgery above the fogs of mysticism into the clearer atmosphere of knowledge and common sense.

Peace and War.

Whenever the acid test of war has been applied the healers have risen to the occasion. Whether Machaon, *ἰητρὸς ἀνὴρ πολλῶν ἀντάξιος ἄλλων*, a surgeon worth a multitude, Ambrose Paré groping towards the truth, or one who served in the Great War, the navy and army surgeon, whether attempting to prevent disease, formerly more fatal than the bullet, to rescue the wounded, or tend their hurts, has ever placed duty far in front of self. Two men only have ever won bars to the Victoria Cross—Martin Leake and Chavasse, *ἀνδρές ἰητροὶ*, both added honour to our profession. They did not see red. Theirs was that cold, clear-cut, "two o'clock in the morning" courage—that courage shown by many another surgeon who, when disaster was imminent, solicitous only for his wounded, with them awaited certain death or capture.

> "Atqui sciebat quae sibi barbaras
> Tortor pararet."

Such is the history in peace and in war of the profession into which you are entering.

This hospital and school in which you will continue your education, and form your medical character has behind it great names, great traditions, and a continuing reputation for good work. It is certain that you will find here greater and more frequent opportunities than you would in some of the larger and more crowded schools for *doing* things yourselves rather than merely watching others do them. For my own part I wish that every one of you had entered and worked here "ab Ossibus usque ad Bacteria," from "the Bones to the Bugs," so that you might be imbued with the esprit de corps and carry the hall-mark of St. George's from "the eggs to the apples" of your professional training, but that at present is not possible.

I have undertaken to-day to speak to you on the subject of "Practice"—the practice of your profession in whatsoever branch of it you may elect to work. Before doing so I think it is very right and proper that I should say something as to your preparation for that work both here and in the outside world.

Factors that Make for Success.

To do well in practice a very sound knowledge of your profession, though by far the most important, is by no means the only factor which makes for success. Personality, presence, tact, sympathy, understanding, and a profound knowledge of human nature are indispensable, and you cannot commence to cultivate these essentials too early. If you, therefore, wish to do well you must become a "man of parts" in every sense of the word. For this reason I urge every one of you to have some interests outside your actual profession—cultivate some hobby. I do not much care what it may be so long as it brings you into contact with your fellow men well away from the bedside, and, if it be possible, takes you into the open air. For some of you this may not be advisable, and your inclinations may lead you to vary your work by taking up some other line of scientific research—well and good—t'will serve. But those of you to whom sport in any form is a real recreation and allurement "grapple it to your hearts with hooks of steel"—so long as you live you will never regret it. Do not confine your efforts to one branch of sport only, you will then not only make a much larger collection of lifelong friends, but a youth thus well spent will fit you both physically and mentally to cope with the hard, exacting work required from you in after life. Play the strenuous games while working here so long as you may be able. Afterwards harass the ball in a milder fashion, slay the grouse, or beguile the fish whenever you get a chance. A sporting reputation will often be of service to you in quite unexpected ways. Early in the war I had to lecture on venereal disease to some thousands of pitmen and other workers at Newcastle-on-Tyne. The chairman of the meeting was evidently rather doubtful how the men would take that which was coming to them. So he proceeded to disinter my long-buried athletic past, and having brought it to light heaved a sigh of relief, and said "I'll just tell my lads that—They'll think a damned deal more of thee as a football player than they will as a doctor."

Do not, however, think that I am putting your amusements and hobbies in front or in place of the real and serious preparation for your future career.

A wise student can combine the two. At the end of 1876 St. George's held the football cup, the athletic shield, and the highest average of passes in all the examinations; and the men who gained the school prizes and passed the examinations were those who played in the fifteen and won the races. "Verbum sapienti satis est."

Twin Rocks of Practice.

You who are now entering this clinical school have surmounted the obstacles of your earlier examinations. I expect some of the troublesome details in the subsidiary sciences will rapidly fade from your memories. Be that as it may, there are two subjects which, if you wish to do really well, you must practically make a part of yourselves—anatomy and physiology. These are the twin rocks on which the whole edifice of your work both here and in practice afterwards is founded and built. What is surgery, even surgery *in excelsis*, but anatomy—anatomy and common sense, while medicine in addition takes unto herself rather more physiology. The General Medical Council, when revising the curriculum last year, was so impressed with the necessity of a continuing knowledge of these two subjects that it was enacted that active teaching of both in relation to medicine and surgery shall be continued during the whole course of professional education, and that the knowledge of students therein shall be thoroughly tested in the final examinations, including the anatomy of the living body and not only that of the subject. Therefore, while working in the wards and school carefully conserve and add to your knowledge of these fundamental sciences.

Whenever you can get a chance *do* things for yourself. Do not be satisfied with watching others demonstrate how they should be done. Under the new regulations for examinations more value will be given for practical work. A brilliant theoretical paper will not, in future, outweigh bad clinical or practical work, as has sometimes been the case in the past, so that no man will take his degree unless he be a capable and practical physician and surgeon. Supplement your reading by the work of your hands on every possible occasion. I most strongly advise every one of you to set his face steadily towards "house" office, either here or, if that be not possible, in some other institution. You will be infinitely better qualified for practice if you have worked as house physician and house surgeon with the help and under the supervision of the staff of some hospital. Not only will the experience gained from your cases and the responsibilities you will have to face be invaluable, but if, as I hope is still the custom here, you teach in the wards as you go round, that teaching will increase your own knowledge and accuracy fourfold. You are working in the "fierce light that beats upon a throne," and should you make a mistake it will be all over the school the next day.

Choice of Career on Qualification.

When you have taken your degree and become qualified, the culminating point of the first stage of your career as a student of medicine—students of medicine you are, and students you will remain until you cease to function—you will naturally give thought to your future, and will seriously consider in which branch of your profession you can best employ your talents and abilities. Those of you who have taken honours and won scholarships will naturally turn towards the higher examinations for the M.D. or the Fellowship, with a view to appointment on the staff of a hospital. If you are well qualified and can give the time and work necessary to obtain and succeed in such a post you can hardly do better. Some of you may intend to specialise in some branch of medicine or surgery. If so, be sure that you know your profession from alpha to omega before you confine yourself to study one department only. To be a really competent specialist a man should have a comprehensive knowledge both of medicine and surgery, and, if possible, should have practised some years before starting on his own particular line of work. Build the house first—fair and strong—add the coping stone and pinnacles of special investigation and research to the completed building. Brudenell Carter was in practice for some years, and served through the Crimean war before he became ophthalmic surgeon to this hospital.

You must remember that the human body cannot be bulk-headed off into various water-tight compartments, only one of which can be torpedoed at a time. The lay public does imagine this. I remember that once when I suggested a surgeon for an operation for carcinoma of the breast, I was met by the friends of the patient with the objection, "Oh, but he is only an abdominal surgeon." And occasionally you will come across even worse instances. Some years ago I was asked to see an individual, and after some little time I discovered that she was consulting, each quite independently of the other, one specialist for her brain and nervous system, a second for her eyes, a third for her skin, a fourth for her heart, a fifth for her liver and digestion, and a sixth (of course) for her uterus, while I, the seventh, poor wretch, was expected to "knit up the ravelled sleeve" and blend into one harmonious whole all these six varied and divergent lines of treatment! I declined the hopeless task. Remember, and never forget, that if you believe, and have exceedingly good reason for believing, that you have forgotten more about the little toe than anyone else ever knew, still that little toe has four intimate and closely connected companions on the same foot, and that a cyclonic disturbance originating in the biggest may even reverberate in the sacred precincts of the smallest. I have in my mind the instance of a friend of mine who, some thirty years ago, told me that one well-known specialist "was burning ulcers off his throat," while another, equally notorious, was "running his gout off through his kidneys with iodine," he having a cavity at either apex.

We cannot get on without specialists. They are invaluable. Some portions of our economy should practically be sacred to them. But when, as has frequently happened, I have been asked what I know of some eminent gentleman—to the public all specialists are eminent—who is supposed to be a specialist for some organ or disease which is so intimately an integral part of medicine and surgery as a whole that every practitioner must have a complete and exhaustive knowledge of it if he is to do any effective work whatever, then it gives me pause to think, and I wonder at the why and the wherefore.

The Services.

Some of you may decide to serve His Majesty and take a commission in the Navy, Army, Air Force, or Indian Medical Service. I am not here to discuss the advantages or disadvantages of each or any of these different Services. St. George's men have done exceedingly well in all of them, and you will carry on the tradition. The Public Health Medical Service, and appointments under various Government departments will attract a certain proportion of you. The degree of D.P.H. is necessary to qualify for these offices. The new regulations, which will shortly come into force, will raise this qualification to the status of an honours degree rather than a mere appendage of letters, and will distinguish those men who intend to devote their life to that which I prefer to call "administrative" rather than "preventive" medicine. During the last few years many attempts have been made to lay down accurately a dividing line between "clinical" and "preventive" medicine—how far the medical officer of health should go in the treatment of illness, and what should be the duties and the attitude of the clinical practitioner to the prevention of disease. For my own part, I have come to the conclusion that whenever I have warned little Jimmy that green apples in the wrong place are a source of acute discomfort, advised that they should be kept from him, and, if required, administered the harmless necessary castor oil, I was in actual fact combining clinical with preventive medicine, and that it was impossible to separate the two. Therefore, I consider that the terms "clinical" and "administrative" best define the scope of the work of the public health and practising branches of the profession.

Public Health.

In these progressive times there is a magnificent future for the medical officer of health. "Prevention is better than cure," and though he will frequently be expected to prevent the unpreventable, and remove the irremovable his opportunities to improve the physical condition of the people will be abundant, and his influence for good on the health of the community enormous. In all circumstances, and on every possible occasion, he should strive to work hand and glove with the practitioners in his district—his work then will be far easier of accomplishment and more satisfactory in achievement than if a state of armed neutrality or open warfare existed between him and them. One drawback, however, there is to service either under the State or any municipal body. To parody the Victorian poet—

> "Red tape is too much with us,
> Signing and certifying we lay waste our powers."

Minutes and reports are doubtless necessary to the supervising departments, but, writing myself down an ass, I often wonder if equal efficiency could not be secured with half the expenditure of ink, paper, and valuable time, which last, on the part of the doctor, might be so much better employed.

General Practice.

The greater number of you will go out from here and start work as general practitioners, or, in other words, you will take up your positions in the first and front line of defence against the continuous attacks of disease and death. In London and the great industrial centres you will be the first to see and appreciate the beginnings, and the earliest symptoms of mischief which, in many cases may be but of little moment, but in others of the gravest importance. In the sparsely populated rural districts you will be even more responsible. It is hardly possible to overstate the importance of such work, be it undertaken in country or town. In either case your motto must ever be "Principiis obsta," and the early exercise of your intelligence and acumen will save many a life, and put a term to years of unnecessary invalidism. However much you may be tempted never palliate symptoms only. Get right down, discover the cause of the trouble, and if possible remove it. You will have the advantage of seeing your cases when it is possible to benefit them. Your supports, the heavy guns, the consultant and the specialist, often have no chance of doing much good, as they may arrive on the scene too late. Therefore, during your preparation for future practice cultivate without ceasing the ability to make an early and accurate diagnosis, coupled with a sound prognosis, in every case you may see, however commonplace and trivial at the first glance it may appear. You can then take whatever action may be necessary, and when required call up your reserves and send out a "S.O.S." in time.

Years ago a St. George's man, a man of experience and knowledge of the world, said to me: "To a man who knows his work well two things are difficult in practice. The first to get into a house; the second, to get out of it." You will find this very true, and though as you grow in experience and status the first may be easier, the second will become increasingly difficult. You are asked to visit a sick person. You will soon find that on many occasions a very urgent summons is dictated by discomfort rather than by danger, while the quiet little note or message, "If you are in this part of the world come and see me some day—I am not feeling very well," may have behind it a grumbling appendix, the little malignant lump calling out for immediate attention, or the beginnings of some definite and serious disorder. Very early in the course of your work you may—you probably will—be confronted with a situation such as you have never had to face during all the years of your training. You visit a person whom you may never have seen before. Apparently there is very little wrong, but after examination you find such unsuspected conditions of disease—hepatic carcinoma, for instance—that a fatal termination is only a matter of a short time. In such circumstances what are you to do? What are you to say? The task is indeed difficult. To combine consideration and mercy for your patient with justice to his relations and yourself may well call for the exercise of the greatest tact and the most profound sympathy.

Cases not Met With in Hospital.

Let me warn you that you will not see in private practice the same sort of cases which you meet with in hospital. By this I do not mean that pneumonia in a private house differs from pneumonia in a hospital ward. The illness, quâ illness, and pathological change, are the same. The sufferers may differ, but that is another story. In a great hospital you have gathered together persons afflicted with severe and pronounced disease, the victims of serious accidents, and cases which, from their nature and environment, are beyond the possibility of proper treatment by the outside practitioner. Therefore you will not see so many grave cases wherever your work may lie. In industrial districts they are more frequent, as the British workman is slow to seek advice unless his ailment is painful or keeps him from work. He calls for aid when his condition approximates to that of the hospital patient. In mining areas you will have to deal frequently with many serious accidents. But if your lot should be to look after the well fed, well clothed, well housed sections of the community, you will be surprised at the small proportion of cases of really serious illness you will be called on to attend. I should astonish you if I were to tell you the number of cases of tuberculosis of the lung which have been under my care during the last 40 years. Since I was house physician here I have only seen three cases of enteric fever and one of glaucoma. Being familiar with all the grave manifestations of disease which you meet with in the wards you are able to go with an exceeding confidence into a house, in the sure and certain faith that whatever you may there find cannot be worse than that which you have habitually seen treated here. Again I repeat that "house" office is invaluable. Above all things, never forget to carry with you into your private practice that habit, the most important of any you may acquire in hospital—the habit of always examining and noting the condition of every organ in every case. You will find that a very large proportion of the mistakes which other people make are not due to any lack of knowledge or skill, but simply and solely to the fact that one or more important organs have not been carefully passed under review.

The work in hospital is done with the aid of every possible appliance—mechanical, chemical, optical, and electrical. Above all things never become slaves to your instruments. Cultivate at all costs that which, wanting a better term, I will call your clinical instinct. Make your diagnosis with your brains, your eyes, your fingers, and your ears, and then bring in your machinery to confirm or disprove your findings. Of late years I have noticed that many men are very chary of expressing an opinion, even upon a fairly obvious case, until they have the way made plain before them by laboratory tests and instrumental assistance. To use the invaluable methods of modern day scientific research in this fashion is to degrade them to the function of crutches, the constant use of which will enfeeble your intellectual muscles, and doom your independent perceptions to atrophy. Let them rather take the place of a walking stick, which will support your steps in rough places without paralysing your limbs. Times without number you will find the eye, the finger, and the stethoscope, used with a trained clinical intelligence, beat the test tube, the X ray, and the swab. Acting on the knowledge thus obtained, you frequently can save much valuable time to the great benefit of your patient. Use to the very fullest extent, but do not abuse, the assistance given to you by science.

Bedside Qualities.

If when you visit a sick person you are fit and well and, if I may use a slang expression, " full of beans," you may be quite certain that you will do that individual much more good than if you yourself were feeling depressed and below par. Some persons call this the " Gift of Healing." Patients are quick, indeed, to notice your manner and derive confidence and hope or the reverse from your demeanour. The convention that the habiliments and physiognomy of the physician should be as sombre as those of his occasional sequela, the undertaker, is now relegated to the limbo of superstitions outworn. If you are by nature " merry and bright," optimistic and high-spirited be thankful that you are so constituted, and exercise those powers to the fullest extent. If you be not, " Assume a cheerfulness though you have it not." A gentleman, who afterwards became a very distinguished surgeon to this hospital, was asked either by Brodie or Cæsar Hawkins (I forget which) to help him at an operation which in those days was always dangerous, and frequently fatal, and afterwards to stay in the house in case of any emergency. The patient died, but left special instructions that the fees due to this young surgeon should be paid three times over, because " he cheered me up."

While holding the most exalted ideals of personal and professional honour, so far as possible, be all things to all men. A hyperæsthetic enjoying bad health, and a breadwinner striving and fretting to get back to his work require very different management if you are to do your very best for both. To accomplish this requires tact—the saving grace of professional success. You will invariably find if you have brought the life, motion, and fresh air of the outer world into the confined atmosphere of the sick room, if you have discussed the iniquities of the Chancellor of the Exchequer, the latest scandal in the law courts, and the great performance of Yorkshire in the county championship, that you will leave the sufferer having done him more good than could be effected by the most cunningly compounded mixture of drugs in the British Pharmacopœia. At all times and in all seasons be very gentle with your patient. The heaviest handed and kindest hearted physician who ever went round the wards of this hospital, what time he severely pounded an extremely tender and sensitive abdomen, thusly exhorted the students standing around: "Never excruciate your patient—you can find out all you want without excruciating your patient—never excruciate a patient." The particular victim in this case had the gift of humour, and fully appreciated the precept and the example.

Take great pains to make an invalid as contented and comfortable as possible. Let the yoke of your restrictions be as easy, and the burden of your directions as light as the exigencies of the case will allow. The bed of sickness is not the bed of Procrustes. You must fit the bed to your patient—not your patient to the bed. The early success of homœopathy was, in the first instance, a revolt against too much calomel, colocynth and senna. The drastic drugs which are the salvation of a navvy are anathema to a thin-skinned, fair-haired, blue-eyed girl. Never prescribe for a person until you have shaken hands with him, and thus assured yourself of the texture of his skin and mucous membrane.

Acceptance of Responsibility.

Every general practitioner should be prepared to accept and face his own responsibilities. I do not mean by this that a fiery, untamed enthusiast should rush in to operate where an expert might well fear to tread, or that a man should be so obsessed by his own opinion of his own skill and importance as to be offended at the idea of a consultation, however difficult and obscure the case may be, but that he should treat and continue to treat until its conclusion, every illness which comes within his powers. I remember, they are all dead now, men of great repute with the public who never by any chance took any responsibility whatever if they could by any means avoid it. If they were confronted with an ordinary conjunctivitis or simple inflamed throat they at once invoked the aid of Sir Adenoid Tonsil, or Mr. Cataract Lens, and stood by while, under the ægis of these great names, nature recovered the patient. Such methods, though probably sound enough as regards these particular practitioners, do not conduce either to the good of the patient or the repute of the profession.

I have said, and even written in my haste, that the medical profession is divided into two classes, fools and physicians. The fool treats the illness, the physician the patient. This fact was impressed upon me years ago by a country unqualified assistant of great experience, in those days when unqualified assistants were lawful. I had treated many cases of pneumonia here, and confidently ordered for a strong full-blooded robust countryman the same treatment which I had seen succeed with the poor half-starved denizens of the Embankment and the parks who were admitted into hospital. The assistant remonstrated with me—of course I knew much better than he did and persisted in my line of treatment. The next day I had to confess that I was wrong and he right, and fortunately gave fresh directions in time to allow nature to save the patient. Be very friendly with Nature. She is ever striving to heal, and though in her efforts to do so she frequently destroys the individual, she means well. Do not rudely obstruct her path. Guide, lead, direct her.

Cures and Charlatans.

You can but seldom claim that you have " cured " a person. I am not now speaking of surgical cases. A gangrenous appendix successfully removed is a " cure," and there are even a few specifics in medicine. The first day I came into office as house physician I was taught this fact by the late Dr. Dickinson, and I have never forgotten the lesson. A girl wished to go out on Tuesday instead of the usual Wednesday. I took Dickinson to see her and he consented to her discharge, and directed me to sign her card. I did so putting as the result " cured." He saw what I had written, and at once said " Cured—who cured her? I didn't. Wilson (the outgoing house physician) would never have the impertinence to say he did. You can't, you only saw her for the first time to-day. Give me her card." Taking it he scratched out " cured," and in his own unmistakable handwriting inscribed " recovered." How true then! How true now! We aid " recovery," we but seldom " cure." You will, however, during the whole of your professional life hear of numberless fearful, wonderful and marvellous " cures " attributed to or accomplished by quacks, herbalists, bone-setters, " Ambubaiarum Collegia, Pharmacopolae hoc genus omne "—unqualified as a rule, though sometimes I am ashamed to say a charlatan disgraces a medical degree. You will *hear* of these " cures," you will *see* the other side of the picture. When an individual considers himself so far superior to the common herd that the orthodox is not good enough for him, and either by grace of nature or in some cases due to the skill and technical competence of the charlatan a good result is obtained, then everyone must hear of it. At all times and in all places he spreads the good tidings abroad, considering his happy fortune a tribute to his own intelligence. And he is ably seconded by the quack—especially if he be a personage in the public eye. Like Mr. Vincent Crummles we may indeed wonder " how these things get into the papers," but there they appear, and the whole matter flares up into that glare of publicity and blazon of advertisement which is the very life blood and breath of existence of the quack, but infamous conduct on the part of a member of a learned profession. Such are the cases of which you will *hear*—you will *see* the failures. No publicity here; no credit here to quack or quacked. It will be your task to attempt to repair the damaged joints, to palliate the sufferings, soothe the downward path, and sign the death certificates for those who come under your care "cured" of tuberculosis, or suffering from malignant disease allowed to increase until operation is neither advisable nor possible. But *few* hear of these disasters. They sink into oblivion—the oblivion of the sacred confidence between doctor and patient. Be very tolerant in all your dealings with such cases. Even in the present day, when we discuss insulin, appendicitis, and the sterilisation of the unfit at every dinner table before the women leave the room, the general public is very unknowing of things medical. "Populus vult decipi et decipiatur."

Cults, Religious and Other.

Very frequently you will come into contact with the votaries of those cults, religious, semi-religious, psychic, and imaginative, which profess to remove all the ills which flesh is heir to, by suggestion, and other means of influencing the nervous system. As with quackery so with these scarcely less harmful phantasies. You will hear only of their virtues. You will experience their vices. But in your haste do not write them all down as pure humbug. Though an abomination to your intellect and intelligence, still as the small boy said of the lie, you may sometimes find them a very present help in time of trouble—especially in those very difficult and unsatisfactory cases in which there is nothing whatever the matter with the patient. I mean by this when he has no actual organic lesion, or definite disease. Great success occasionally attends an attack along these lines in cases of purely functional disorder. Many years ago with the cordial approbation of the patient's father and the aid of the late Lord Lister, we successfully exorcised an entirely imaginary needle which in less than a week simply raced from the hip to the knee, causing, during its express journey, very acute discomfort to a hyperæsthetic young lady and her long-suffering friends and relations. We employed the methods of modern-day Christian Science, faith-healing, higher thought and pseudo-surgery. Our efforts were crowned with success. The needle troubled her no more.

Year by year you will see the rise and follow the decline and fall of many new diseases, of many loudly vaunted treatments, and will regret the premature discussion in public of matters of real scientific interest while yet in the experimental stage. It will be your lot to watch an endless procession of fetishes, each one surviving until pushed out of the limelight by its successor. In the morning they flourish like a green bay tree, in the evening they are cut down, dried up and withered.

"Truditur dies die
Novae que pergunt interire lunae."

There is a story of Sir William Gull, in his day a very great physician, and a consummate man of the world, which though old will bear repetition. A lady asked him whether she should try some much advocated new treatment. Gull replied "Certainly, my dear lady, most certainly—only mind you go while it cures."

"Time like an ever rolling stream,
Bears all these 'fads' away.
They fly forgotten as a dream
Dies at the opening day."

Relations with Colleagues.

In the course of your future work you are bound to come in contact with your fellow practitioners in many ways, and on many occasions. In our profession we are extremely individualistic, and it is certain that sometimes there will be friction between us, sometimes even leading to a quarrel. This is always unfortunate and generally unnecessary. If you make a rule to put yourself in the other man's place, and act as you think he should act towards you, fighting will be at a discount and ethical rules superfluous. Should you ever hear from a lay person that a doctor has given some extraordinary opinion or stated some impossible fact, don't you believe it. A dear old friend of mine once asked me if it were possible for a person to have some fearful, wonderful and impossible condition of disease. I answered "No." She replied "But her doctor told her she had." I said "No doctor could have told her such a thing. It is medically and surgically ludicrous." "But," she insisted, "So-and-So distinctly told me that was what her doctor said." My reply finished the discussion—"I am quite sure he did not—for I am So-and-So's doctor." The moral is obvious.

If a medical practitioner can find the time he should, as a citizen, interest himself and, if possible, take part in the public work of his town or district. As members of the public health committee of any municipality two or three unofficial doctors will often be the little leaven which leavens the lump, and their timely advice and influence may turn well-meaning, but ill-informed city fathers from some action which might gravely affect the health of the community.

Whether in the future you may become consultant, specialist, or general practitioner, always bear in mind that you are not dealing with inorganic material in a test-tube, or crucible, but with living human organisms each differing from every other, complete and perfect in itself.

"Of all God's workes which doe this worlde adorne,
  There is no one more faire and excellent
Than is man's body, both for powre and forme,
  Whiles it is kept in sober government:
But none than it more fowle and indecent,
  Distempered through misrule and passion bace,
It groes a monster, and incontinent
  Doth loose his dignity, and native grace;
Behold, who list, both one and other in this place."

These words are as true to-day as when Spenser wrote them nearly 400 years ago, so let your advice ever tend to this ideal, always urging and leading on those who entrust themselves to your care to attain that "Mens sana in corpore sano" the "summum bonum" of human existence and happiness.

The words which I have spoken to you to-day naturally apply chiefly to that form of practice of which alone I have experience, in which you work with your patient as individuals subject only to the common law of the land, and the ethics of your profession. But if in this present time any of you either by inclination, or of necessity, choose to enter into an engagement to treat persons by contract, then most of what I have said applies also to that form of practice. Should you make such a bargain you will carry it out both in the spirit and the letter. Whether or no you should undertake such work is for yourselves to decide.

Rewards and Friendships.

In whichever branch of your profession you may finally practise you will make lifelong friendships. You will acquire merit when you deserve blame, and blame when worthy of praise. These things all come into the day's work and a philosopher regards them with equanimity.

You have the world before you. You are the heirs of the ages. It is your privilege to begin where we leave off. The progress in every branch of our art which we have seen in our time is marvellous, and when you in your turn, "forty years on," look back, all the signs portend that you will have left even more behind you. Where we laboriously treated disease with drugs and diet the surgeon now, with a short circuit, gives sometimes in weeks the relief we failed to obtain in years. A short cut indeed! The gynæcologist has relegated to the scrap-heap of worn-out, disused machinery the instruments for craniotomy. With his mother MacDuff in his hundreds walks the streets, a living testimony to aseptic surgery.

"For those of us whose lot, sooner far than later, will issue from the urn—for those of us whose blunted lancet and perished stethoscope, like the arms and war-weary lute of Horace will soon adorn the wall, the time is at hand when we must humbly hope that, with that great poet, we may be able to say, 'Militavi non sine Gloriâ.'"[1]

You are now straining at the leash, crouched for the start, ready and eager to grasp the bâton which will send you on to run your allotted portion of the never-ending relay race against the teams of suffering and death; but when, in your turn, you hand on your trust to those who will follow after could we but burst the eternal exile of the boat and re-visiting the glimpses of the moon see the world, as you will leave it, healthier and therefore happier, rejoicing in your prowess, we should indeed be proud. We are confident that great will be your efforts, great your success, and speeding you on your way I salute you—"Ave atque Vale."

---

[1] "Omnes eodem cogimur, omnium
Versatur urnâ serius ocius
Sors exitura et nos in æternum
Exsilium impositura Cymbœ."

"Et militavi non sine gloriâ,
Nunc arma defunctamque bello
Barbiton hic paries habebit."

TEAM-WORK IN NATURE.

Delivered on Oct. 2nd at the Opening of the Winter Session of the Middlesex Hospital.

By SOMERVILLE HASTINGS, M.S. Lond., F.R.C.S. Eng.,
SURGEON IN CHARGE OF THE EAR AND THROAT DEPARTMENT.

I am informed that the primary object of an introductory lecture is to congratulate those students who are just commencing their medical studies on the choice of a noble profession, and give them some useful advice on entering it. I shall omit the useful advice, but I would, nevertheless, like to address myself mainly to those students who are here for the first time.

The Struggle for Existence.

Darwin and Wallace have taught us that "the struggle for existence" and the "survival of the fittest" are the principal factors in organic evolution. But Darwin is quick to add, in his monumental work the "Origin of Species," that he uses the term "the struggle for existence" in a large and metaphorical sense, including dependence of one being on another. That Darwin appreciated the interdependence of one organism on another is shown by the well-known story of the cats and clover. The success of the red clover crop depends on the fertilisation of its flowers. Humble bees are the only insects that visit these flowers, and if humble bees are absent no seeds will be set. The chief enemies of humble bees are field mice, which destroy their comb and nests. "Probably two-thirds of them are destroyed all over England." Cats, which destroy mice, may therefore determine the success or otherwise of the clover crop. Darwin points out how in numberless animal societies the struggle between separate individuals for a means of existence disappears and is replaced by coöperation, and how that substitution results in the development of faculties which secure to those animals the best conditions for survival. It is, therefore, plain that those who would have us look upon Nature as a perpetual struggle among half-starved individuals thirsting for each other's blood are only showing us one-half of the picture.

It would be possible to cite innumerable examples—bees, ants, corals, the migration of birds—to show how much of team-work there is among creatures of the same sort. But plants and animals of different kinds also coöperate together to a much larger extent than was formerly supposed, and I might easily spend the rest of my time in reminding you of how plovers live with crocodiles, and sea-anemones with hermit-crabs, to the advantage of both; of how tiny sea-weeds live in the interior of marine worms and each gains by the association; of how the pollen of flowers is carried to other flowers by bees and other winged insects, who are rewarded for the work they do by the honey they collect.

Team-Work between Fungi and Other Organisms.

This afternoon, however, I want to confine my remarks to one of the lowliest groups of plants, the Fungi, and describe to you a little of the recent work that has been done in connexion with team-work between these and other plants and animals.

The Lichen.

And first of all, let us look at the Lichens. Every rock, fence, or tree which remains undisturbed for a year or two in the country gets covered over with lichens. I say in the country advisedly, because lichens will not tolerate the smoke of towns, and with one exception, "the London Lichen" (*Lecanora galactnia*), no lichens are to be found within many miles of the centre of London. It is said that the authorities of the Zoo, ignorant of this fact, covered the Mappin terraces with lichens from the country, and were not a little surprised that none of them would grow. To the medical student lichens are chiefly of interest because litmus is prepared from one of them. In the old days of medicine things were different. It was then believed that Providence had placed on plants "signatures" or resemblances—more or less vague—to parts of the human body. For instance, the skull lichen (*Parmelia saxatalis*), sometimes found growing on old bones lying in the open, was considered worth its weight in gold for the cure of epilepsy, and it was especially prized when taken from the skulls of those who had been hanged or executed for offences.

Lichens are important in Nature because they form an advance guard of organic life. They grow in deserts, and on mountains reach right up to the limit of perpetual snow. On bare rock flattened lichens first appear; more leafy varieties follow. Around these soil slowly collects, and thus the way is prepared for other plants.

A lichen is really a dual organism, being composed of a fungus united with a green plant (an alga). Now, all fungi, however much they differ, have this in common: that being devoid of green colouring matter (chlorophyll) they are unable to break up the carbonic acid gas of the air and obtain their carbon from it. Like ourselves, therefore, they have to obtain their food ready made from other plants or animals. If a lichen be cut into very thin slices and examined under a microscope, it will be seen to be composed of a network of fine colourless tubular cells (the fungus), enclosing within its meshes, especially near the surface, a number of bright green algal cells. These green cells are closely allied to similar cells to be found abundantly in moist situations—on tree trunks, walls, &c. The two constituents of a lichen can be grown apart under suitable conditions. In most cases the alga gets on fairly well, for it is used to living alone, but the fungus is less happy. If the two are re-united a lichen is once more formed.

Now, what is the exact relationship between the fungus and the alga of a lichen? Do they "love, honour, and cherish" one another, or is the fungus very much the senior partner of the firm? The view generally held is that both constituents derive direct benefit from the alliance; that the alga obtains water and mineral matters collected from the soil by the fungus in exchange for carbon products extracted from the air by the aid of light. Recently two Russian botanists, Elenkin and Danilov, have revived the old theory that the fungus is parasitic on the algal cell. They state that fine branches of the fungus pierce the algal cells and, forming a delicate network within, rob them of their cell-contents. A few years ago Robert Paulson and I spent much time in cutting and staining sections of different sorts of lichens. In this work we found the method of staining introduced by Victor Bonney especially valuable. We were able to show for the first time that the algal cells produce their spores normally within the lichen, but we never saw a single algal cell penetrated by a fungus thread.

Nitrogen Fixation in Nature.

Before turning to examples of team-work by fungi and flowering plants, I would like to remind you of a few rather dry facts of chemistry. The ultimate end of all living matter is decomposition, decay. The carbon compounds break up into water and carbonic acid gas, and the carbonic acid gas is returned to the atmosphere. The nitrogen containing compounds or proteids are finally resolved into ammonia and nitrogen, and the nitrogen leaks away into the atmosphere. The water and carbonic acid gas can be used again by green plants, and with the help of light built up once more into those complex substances of which they are composed, but they cannot touch the nitrogen at all. The constant tendency of ordinary organic life is therefore to increase the nitrogen in the air at the expense of that contained in plants and animals, and had not Nature provided some means of replacing the nitrogen thus lost the world would very rapidly become uninhabitable for plants and animals. That cultivated plants often suffer from nitrogen hunger was perhaps the most important agricultural discovery of the last century, and to make up this deficiency thousands of tons of nitrates from South America and sulphate of ammonia from the gas works are added every year by farmers to their land. It is true that every flash of lightning results in the combination of small quantities of free nitrogen to form ammonia and this is brought down to earth by dew and rain. But the total amount of ammonia thus carried down does not exceed 5 lb. per acre per year—an amount entirely inadequate to replace that lost by the ordinary processes of decay. At the end of the last century, therefore, it became evident to scientists that there must be some way as yet undiscovered by which Nature carries out the combination of free nitrogen to make it available to organic life.

Root Nodules of Leguminosæ.

For centuries it has been known that certain plants have a wonderful power of rendering barren tracts of land capable of producing crops. Thus Pliny tells us that "The bean fertilises the ground in which it has been sown as well as any manure." Waste land in Germany and America has been rendered fertile by the planting of lupins. Now it is only leguminous plants like the pea, bean, lupin, clover, and the like that have this power and they all have nodules on their roots. This is easily seen when a bean or lupin is pulled up. These root nodules are the key to the situation, for in them is taking place what is to us the most important example of team-work in Nature for without it we could not live.

A very small bacterium (*Pseudomonas radicicola*) is met with in abundance in the soil, more especially where leguminous plants have been grown. When it comes across a root hair of a leguminous plant it punctures the cell wall and enters one of the cells. There it multiplies rapidly until a mass of closely packed rod-shaped bacteria embedded in a gelatinous substance is produced. This infection thread, as it is called, passes inwards from the cells of the root hair to those of the root from which it grows. The irritation thus caused results in rapid multiplication of the cells of the root and the formation of a nodule or swelling containing cells crowded with bacteria. These root nodules have been shown experimentally to absorb nitrogen from the air and the bacteria they contain become filled with nitrogen-containing food substances. But about the time of flowering a change occurs. A ferment is secreted which dissolves the bacteria and the valuable food they contain. After this has been absorbed by the plant the nodules shrivel and decay. A few of the bacteria, however, escape destruction and find their way into the soil. These root nodules undoubtedly show a "community of interest" between the two partners, but whether we can consider it a true example of symbiosis is, at least, open to question. The bacteria score at first in that they acquire a comfortable home with everything found, but in the end the higher plant comes off best.

Other Flowering Plants.

A careful study of flowering plants teaches us that nearly all have fungi associated with them at some stage or other of their life-history. With the Darnel (*Lolium*), a common grass, the fungus is there all the time—from the cradle to the grave, so to speak. The grass appears perfectly healthy and is thought to score in that the fungus threads in the seed form a store of food easily absorbed by the young plant. In return for this the fungus is housed and fed and allowed to pass from one generation to another in the seed.

In the Heather (*Calluna vulgaris*) a fungus is also found in every part of the plant, but though present in the seed coat, it never extends directly to the seed. If heather seeds dipped in strong disinfectant and then washed are sown on sterilised soil they germinate imperfectly, develop one or two leaves, and then die. If, however, the fungus obtained from the heather is added to the soil on which such seedlings are growing they develop normally and form healthy young plants. The heather absolutely refuses to grow without its fungus partner.

[Mr. Somerville Hastings here described how a fungus is constantly present in the roots of orchids, and how the seeds will not germinate without it.]

Toadstools and the Mycorrhiza.

For many generations people have thought that there was something mystic and uncanny about toadstools. Because they come up quickly and have no obvious root they were thought to have been placed in woods and fields by witches and fairies, and it was told how the fairy-ring toadstool (*Marasmius oreades*) always came up where fairies had danced at night. Then scientists came along, and finding that toadstools were always attached to fine filaments of a fungus plant ramifying in the soil, they thought they had solved the problem. They told us that the fungus plant of which the toadstools were but the fruits, formed for the purpose of producing and distributing spores, lived on decaying animal and vegetable matter in the soil, and they proceeded to give the toadstools themselves many and long Latin names. But when the scientists turned their attention to trying to work out the life-history of these same toadstools, as they are now doing, they found that things were not always quite so simple and that an increasing number of toadstools were found to be constantly associated with some other plant. The Fly Agaric (*Amanita muscaria*), with its beautiful red top covered with white spots, for example, is invariably found close to where birch trees are growing or have recently grown. When the fine filaments from a toadstool are carefully traced to their source (a by no means easy task) they are often found to end in the roots of some tree or herb. In a few cases this association is definitely harmful to the plant—the fairy-ring toadstool plant, for instance, is said to grow parasitically on the roots of grasses—but in most cases the herb or tree appears to be in no way inconvenienced by the presence of its fungus partner. The association of fungus with the roots of a higher plant is spoken of as a mycorrhiza. If the dead leaves around almost any woodland tree be scraped away, numerous fine branching rootlets will be seen passing in all directions through the decaying leaves The ends of the rootlets appear swollen and with a pocket lens fine fungus threads can be traced to them. When the threads reach the rootlets they surround them with a closely woven mantle, but in the case of most trees do not penetrate to any extent into the tissues of the root. The immediate effect of the fungus on the rootlets is to arrest their growth in length, and as a result of this more frequent branching occurs. Already some 80 different associations between fungi and woodland trees have been described, and this does not by any means complete the list. Indeed, mycorrhiza would appear to be constantly present during the life of most forest trees. It is certainly present in young seedlings of the birch, beech, and edible chestnut. Paulson states that mycorrhiza has formed on birch seedlings growing on light soil within a month of the germination of the seeds, and although he has examined a large number of seedlings of all ages he has never yet seen one on which mycorrhiza had not formed or was not forming. The presence of mycorrhiza can hardly be really harmful to the birch seedlings, for such plants grow as much as two feet during the first year.

The Meaning of Mycorrhiza.

We are now in a position to inquire what is the real meaning of mycorrhiza. Is it useful to fungus or higher plants, or to both? How did it arise in Nature? In the first place, mycorrhiza is no new-fangled device. Examples are found around roots of fossilised plants from the Devonian and lower coal measures. Again, it is widely distributed in Nature, and has been described in association with liverworts, mosses, horsetails, club mosses, ferns, conifers, and flowering plants. Gallaud carefully examined the roots of 35 different flowering plants of widely separated genera. In 30 he found fungi present with great regularity and obtained them also with less constancy from the roots of four of the others. That mycorrhiza is generally harmless to plants would seem to be borne out by the examination of birch seedlings, and Gallaud's observations on the cuckoo-pint (*Arum maculatum*), a plant which is found sometimes with and sometimes without mycorrhiza. Gallaud could find no difference between infected and non-infected plants attributable to infection.

In this connexion the following observations by Paulson are not without interest. The story is still incomplete, but as far as it goes it would seem to indicate that the birch has been "fitter to survive" when its young root is supplied with fungus. The birch has a small winged seed. The styles formed in the early spring dry up and remain persistently attached to the seed. Close examination of the seeds before germination, and even before they have fallen to the ground, has revealed the fact that fine fungal threads often exist around these styles and stretch from one style to another. Between the styles is a small hole in the seed coat through which the young root is bound to pass when the seed germinates. On the surface of the young root are a number of hooks which prove remarkably effective in catching the angled weft of fungus threads, tearing them from the styles and carrying them downward to the soil.

The association between the "stump tuft" toadstool (*Armillaria mellea*) and a Japanese orchid (*Gastrodia elata*) is of importance as it would appear to give the clue to the origin of mycorrhiza. The stump tuft is one of the commonest of British fungi. It often forms large groups of toadstools at the root of a tree or stump. The fungus is a destructive parasite, and more trees are probably destroyed by it than by any other parasitic agent. Having infected one tree it passes through the ground to the next in form of thick black masses of fungus threads resembling leather bootlaces. When it has killed a tree it forms similar masses between the wood and bark. These become obvious when the bark has decayed or has been removed. Although this fungus usually attacks trees it is not above destroying potatoes if its root-like threads come across them.

The Japanese orchid *Gastrodia*, which grows in woods, forms tuberous masses resembling a large potato buried in the ground. Every year these tubers give off offsets just as a potato does, but no leaves or flowers are in the ordinary way produced. Each year the offsets become progressively smaller until finally they are incapable of further growth. If, however, one of the root-like masses of fungus threads from the stump tuft comes in contact with the orchid tuber a wonderful change occurs. The fungus fastens on to the tuber, and its threads penetrate its outer covering. But instead of succumbing to the attack and giving up its store of nourishment as the potato does, the orchid is able to hold the fungus in check and make use of the food it brings. As a result of this a full-grown offset is produced, which the next year develops flowers and presumably seeds as well. Here we have a fungus well known all over the world as a destructive parasite. It attacks the thickened underground root of an orchid, but becomes worsted in the struggle and is made to give up some of the booty it has stolen from the forest trees around.

May not mycorrhiza have arisen somewhat in this way? May not the higher plants have developed an immunity against fungi originally parasitic on their roots, so that they are now able to hold them in check and actually derive benefit from them?

Dispersal of Spores.

But it is in connexion with the dispersal of their spores that some of the best examples of team-work between fungi and other creatures is seen. Many toadstools are frequently eaten by slugs, and the germinating spores of several kinds were found by Voglino in the digestive tracts of slugs that had eaten them. Further, this observer showed that the spores of other species that could not be made to grow elsewhere germinated readily in the fluid from the digestive tract of a slug.

There are a large number of fungi especially characteristic of tropical regions, that show an unmistakable adaptation for the dispersal of their spores by insects. Perhaps I shall explain my meaning best if I give you a brief description of the stinkhorn (*Phallus impudicus*) common in our woods. In its early stages it closely resembles an ordinary hen's egg with a softened shell lying half embedded in the soil. When mature its outer gelatinous coat ruptures at the top, and the stalk, which had previously resembled a compressed sponge, rapidly expands until in from one to three hours it has increased its length from an inch and a half to six or eight inches. Carried aloft by the white stalk is a conical cap covered by a dark-green glutinous substance in which are embedded millions of spores. After a few hours, especially in the presence of light, the dark-green slimy material begins to give off a fœtid and disgusting smell. Bluebottles and smaller flies, attracted by the smell, eagerly devour the dark-green slimy material, and so greedy are they that but rarely do we find a fully developed stinkhorn with any trace of the dark slime upon it. The spores pass unchanged through the insect's body, and in this way their dispersal is effected.

Here we have a wonderful piece of fungus mimicry. In colour, consistency, and odour the spore-containing mass closely resembles the putrescent substances which form the normal food of blow-flies; and that insects are taken in by it is shown by the fact that they not infrequently lay their eggs on the fungus and around. Again, the timing arrangements are very perfect. While the spores are maturing they are carefully protected, and not until they are ready for dispersal are they exposed. They are then raised up on a white stalk which is easily seen from a distance. Other members of the class are brightly coloured. The lattice fungus (*Clathrus cancellatus*) is bright red all over and the dog-stinkhorn (*Mutinus caninus*) is red at the top. Some of the exotic forms resemble flowers. An Australian species (*Lysurus australiensis*), which came over to this country with fodder, has this appearance.

It is well known that edible truffles are eagerly sought after by pigs and greedily devoured by them, and the fact that these fungi are only strong-smelling when quite mature and filled with ripe spores suggests that this must be something of a coöperative arrangement, and that it is really to the interest of the fungus to be thus eaten. The false truffle (*Elaphomyces*) is also regularly dug up and eaten by squirrels and rabbits, and gnawed specimens are often seen where these animals have been burrowing. The rabbit apparently eats the fungus in the burrow, but the squirrel digs it up first. Spores of the false truffle have been found in the fæces of wild animals, and no other method for the dispersal of the spores of the false truffle is known.

These are a few examples of team-work. When you visit the wards of the Middlesex Hospital you will see even finer examples. There you will find physicians, surgeons, sisters, nurses, not to mention the humble specialists, all united in the single purpose of healing the sick. In the medical profession the value of team-work has been recognised from the earliest times. When an engineer finds out a new process he patents it, so that none but he may use it. When a doctor makes a discovery it is the tradition of his profession that he should publish it to the world, so that all his colleagues and their patients may benefit thereby. For this reason as well as for others, I congratulate you who are joining us to-day on the choice which you have made.

EARLY EXPERIENCES WITH INSULIN IN THE TREATMENT OF DIABETES MELLITUS.

BY NORMAN BURGESS, B.A. CAMB.;
J. M. H. CAMPBELL, M.D. OXF., M.R.C.P. LOND.,
HILDA AND RONALD POULTON FELLOW;
A. A. OSMAN, M.R.C.S.,

PARSONS RESEARCH FELLOW;
AND
E. P. POULTON,* M.D. OXF., F.R.C.P. LOND.,
PHYSICIAN TO GUY'S HOSPITAL.

(From the Medical Investigation Department, Guy's Hospital, London.)

SEVERAL publications regarding the uses and properties of insulin have already appeared in this country, notably those by Banting, Campbell and Fletcher,[1] and by McLeod,[2] but hitherto little detailed information has been published as to the actual results in individual cases. The following investigations have been carried out by us in connexion with the joint scheme of work on insulin initiated by the Medical Research Council. The methods used were: Blood-sugar, Folin and Wu[5]; blood-bicarbonate, Van Slyke, Stillman and Cullen[8]; alveolar CO_2, as described by Campbell, Hunt and Poulton[4]; urinary sugar, Benedict[12]; total ketones (aceto-acetic and β-oxybutyric acids expressed as acetone), Van Slyke[6]; and Van Slyke and Fitz,[7] ammonia by formol titration, urea by hypobromite.

Treatment of a Refractory Case.

This case was specially chosen for treatment in the first place as the patient had on previous occasions been under the care of one of us and we had watched the disease making rapid progress.

CASE 1.—Male, aged 17½, had had the disease since March, 1921. He was under treatment in Guy's Hospital in May, 1921, and responded well to fasting and dietetic treatment, since the blood-sugar at 3 P.M., nine days after the beginning of the treatment, was 0·08 per cent. No sugar was passed on a sufficient diet, containing 4 oz. of bread and plenty of 5 per cent. vegetables. He was sent out on a diet containing 2 oz. of gluten bread, so that he was a long way within his carbohydrate tolerance. He was readmitted in July, 1922. His weight had increased by a stone. He had been eating porridge for three months. There was much sugar in the urine and much ketosis. He became sugar-free with fasting, but the sugar returned at once on beginning a diet of vegetables, protein, and fat.

Readmission to Hospital.—He was readmitted in March, 1923, for insulin treatment. There was much ketosis; he was feeling weak and sleepy, and it was thought he would not have lived more than a few months.

The patient was under treatment with insulin in hospital for 108 days. The extreme severity of the case is one of the reasons for describing it in some detail. It was found that at least 75 units of insulin were required each day to keep the blood-sugar within reasonable limits and the urine free from sugar. The diet was varied to some extent, but the calorie value was rarely above 2000, so that it could not be said to be excessive, considering that the patient was walking about. As it was he often felt hungry. His body-weight increased from 129 lb. to 150 lb. at the end of the treatment. During part of the time he was allowed practically unlimited 5 per cent. vegetables in the form of greens, tomatoes, salad, rhubarb, &c., and he used to take about 32 oz. a day. During the last month of his treatment the amount was reduced to 16 oz. Graham and Harris[13] have emphasised the importance of restricting as far as possible the amount of carbohydrate in the diet when giving insulin. We have adopted the same plan from the beginning of the treatment; for it seemed to us that only by such means would it be possible for a patient to regain some carbohydrate tolerance.

It is, of course, difficult to exclude the possibility of the patient's stealing food. However, he was an educated boy and understood the reason for his treatment, and we believe he was honest. At one period he was kept under lock and key in a private ward for some days, and no marked difference in the blood- and urine-sugar was observed.

We can thoroughly confirm all that others have said about the beneficial effects of insulin treatment in his case. His body filled out and his skin became softer and smoother, and his hair more glossy, and he had the appearance of an extremely healthy young man when he left the hospital. His constipation vanished and he noticed that emissions, which had disappeared since November, 1922, returned 14 days after beginning the insulin. The latter was given in three equal doses at 6 A.M., 12 noon, and 6 P.M. each day before meals. At first we used what we had ourselves prepared in the laboratory by arrangement with the Medical Research Council; but the commercial preparation was employed as soon as it was available. No serious local trouble was experienced in spite of the numerous injections. The blood-sugar was nearly always examined at 11.45 A.M., just before the mid-day dose of insulin.

Progress of Case.—To indicate the progress of the case, the average excretion of sugar, acetone bodies, &c., has been taken for various periods, when the conditions of diet, insulin dosage, &c., remained constant (see Table I.). There was a preliminary period, when the diet contained 2 oz. of bread. During three days there was an average excretion of 132 g. of sugar and 8·2 g. acetone. After fasting for three days the blood-sugar was 0·23 per cent., but rose above this figure when a diet of vegetables, proteins, and fat was given, in spite of the administration of 24 units of insulin daily. However, the excretion of sugar and ketones and the ammonia index were less when the insulin was given than when it was omitted during the next period. Only when a dose of 40 units was combined with a fast day did the sugar and aceto-acetic acid in the urine practically disappear. Then followed two periods of seven days on the same diet, when the dose of insulin was 60 units and the excretion of sugar and ketones was much less than before the fast day. During part of this time, as already stated, the patient was locked in a private room so as to exclude the possibility of his taking carbohydrate of his own accord. On increasing the dose slightly to 65 units the urine-sugar and ketosis were practically abolished, though the diet remained the same, and he had definite hypoglycæmic symptoms—viz., headache, giddiness, shakiness, sinking feelings, and hunger. The blood-sugar at the height of the symptoms was found to be 0·095 per cent. These feelings came on in waves, and there was also profuse sweating. He had noticed flushing and increased sweating when the blood-sugar still remained high. This point is referred to later.

The amount of insulin was at once reduced to 50 units, and he remained sugar-free for three days. As his blood-sugar rose to 0·19 the amount was again increased to 60, but in spite of this sugar appeared in the urine for a period of eight days. Although the calorie value of the diet was increased a little by the addition of fat, he again ceased to pass sugar for seven days and his blood-sugar fell to 0·16 per cent. Wishing to bring this figure still lower, we increased the amount of insulin to 65 units daily, but in spite of this during the next five days he excreted 11 g. sugar daily, and his blood-sugar rose to 0·22 per cent. On increasing the amount to 75 units daily he became sugar-free for nine days, but then passed 22 g. of sugar on one day with a blood-sugar content of 0·18. Suspecting that the large supply of 5 per cent. vegetables was responsible for the sugar, we reduced them to 4 oz. daily. His blood-sugar fell progressively from 0·18 per cent. to 0·13 per cent., and a mere trace of sugar was passed. He was then given 16 oz. of 5 per cent. vegetables, and after this no further change in his diet was made. His blood-sugar varied from 0·13 to 0·20, but he only passed traces of sugar as long as he was free from infection.

From the description just given the patient appears to be subject to variations in the severity of his complaint. For instance, examining the blood-sugar figures for the days preceding his hypoglycæmic symptoms they show the beginning of a remission (0·26 per cent., 0·25 per cent., 0·19 per cent.), thus explaining the marked fall in blood-sugar apparently produced by increasing the insulin from 60 to 65 units. The exacerbation of symptoms, as shown by a rise in blood-sugar and glycosuria, was often associated with infection, such as a cold in the head, and there was sometimes a slight rise in temperature. In particular towards the end of the treatment he had a sharp attack of tonsillitis with a temperature of 102·8° F., and he passed a measurable amount of sugar—viz., 8 g. per diem.

---

* Working on behalf of the Medical Research Council.

The blood bicarbonate was estimated at the beginning of the treatment. It rose to normal at a time when the patient was still passing measurable though small amounts of ketones.

The Action of Insulin on Ketosis.

One of the most striking effects of insulin is the rapid fall in ketosis which follows its administration. Davies, Lambie, Lyon, Meakins and Robson[3] observed a fall in the blood ketones beginning within an hour or so after injecting insulin; in association with this there was a rise in blood bicarbonate and a fall in blood-sugar. We have carried out observations upon somewhat similar lines, and in addition we have determined quantitatively the ketones in the urine. Since there is a simultaneous fall of ketones in both blood and urine, it is clear that insulin acts not by causing an increased excretion of ketones, but by preventing their formation in the body, or perhaps actually metabolising them in some way.

The rapid action of insulin was well illustrated in Case 2.

CASE 2.—Male, aged 9 years, seen by one of us in conjunction with Dr. R. G. Pollock, of Warlingham. The disease began acutely in January, 1922. At the beginning he had done moderately well with dietetic measures, including weekly fast-days, and the urine had remained sugar-free for certain periods, although he had been allowed some starch in his diet. Just before treatment the sugar had shown a rapid increase and there was much ketosis. The blood-sugar was 0·35 per cent. Insulin, 10 units, was administered the next day at 6 P.M. In three and a half hours the blood-sugar was 0·11, but had risen to 0·4 24 hours later. The percentage of sugar in the urine fell from 4·6 to 0·4 in six hours. The alveolar CO_2 rose from 21 to 28 mm. in three and a half hours. The urine collected for 12 hours before the insulin contained 10·1 g. total acetone, and that collected for 12 hours after only contained 1·6 g.

CASE 3.—Table II. contains the figures obtained in this case, a female, aged 29 years, whose disease began in August, 1922. An injection of 10 units produced a fall in blood-sugar from 0·27 to 0·12 in two hours, and three hours later the blood-sugar still remained low. Sugar disappeared from the urine for at least six hours. The fall in the total ketones of the urine was also marked. There was a small rise in alveolar CO_2. The ammonia index (percentage of total nitrogen excreted in the form of ammonia) rose slightly, because there was a rather bigger relative fall in the output of total nitrogen than of the ammonia. The blood bicarbonate (molecular concentration of $NaHCO_3$) showed an increase from 0·025 to 0·029 in two hours.

CASE 4.—Male, aged 38, admitted on May 27th, 1923, for pneumonia and pleurisy. He developed diabetic coma soon after admission. (He had been previously treated in January, 1923, by one of us by fasting and dietetic measures, but continued to pass some sugar in the urine with a blood-sugar of 0·33 per cent.) The blood was taken when he was comatose (see Table II.) at 11 A.M. The blood-sugar was 0·56 per cent.; the plasma bicarbonate was reduced to 0·008 (normal 0·034); and the concentration of blood ketones was 0·18 per cent. He was given an injection of 40 units of insulin with 50 g. of dextrose, and 2 pints of sterile normal saline through a nasal tube, and subsequently 1 pint of saline hourly for six hours. The blood was examined again at 4 P.M. The blood-sugar remained unaltered, so that the insulin had just neutralised the effect of the dextrose given. The plasma bicarbonate had increased to 0·013 and the blood ketones had diminished to 0·12 per cent. There was an associated fall in the amount of ketones excreted in the urine.

Shortly after the first dose of insulin the patient returned to consciousness and the pulse improved. The intake of fluid was continued, after the second dose of insulin, and sodium bicarbonate was ordered by mouth. At midnight the patient suddenly collapsed and, in spite of a further dose of 20 units of insulin, died within an hour or two. This case is not a fair test of insulin treatment in diabetic coma owing to the pulmonary complications present. We have since treated successfully an uncomplicated case of diabetic coma.

Several things emerge from a critical examination of the analyses in this case. A figure of 16 for the ammonia index is surprisingly low considering the extent of the ketosis, and there was a rise to 21 rather than a fall, when the ketosis became less. The plasma bicarbonate was extremely low, corresponding to a very high concentration of blood ketones. In Table II. the excretion of ketones in the urine is given as 0·87 g. per hour before the insulin. This figure is probably too high, because the bladder was not emptied with a catheter at 8 A.M., and at this time the patient was more or less unconscious. Consequently, the 636 c.cm. of urine collected at 11 A.M. were probably secreted over a longer period than the preceding three hours. The amount excreted from 11 A.M. to 4 P.M. was only 0·28 g. There was also a fall in percentage of ketones in the urine from 0·41 to 0·26. Hence, the decrease in blood ketones was due not to increased excretion, but to diminished production (or increased destruction) in the body. In fact, considering the high value of the blood ketones at 4 P.M., we must look upon the small output in the urine as indicating some failure on the part of the kidney to excrete them.

Our case is of some importance since there is at present a tendency not to prescribe sodium bicarbonate and other metallic bases in cases of diabetic coma. Sodium bicarbonate was not ordered in the present case until we had been made aware of the very low value of the plasma bicarbonate. This case convinces us that it is most important to give sodium bicarbonate and other alkalies in moderate quantity whether by mouth, or intravenously, as soon as possible in the treatment. It is unsafe merely to arrest the production of ketone bodies by means of insulin and dextrose. There is some further evidence that this failure of excretion was due to the body being impoverished by loss of metallic bases. The fall in plasma bicarbonate in severe cases is usually regarded as compensating for the large amount of β-oxybutyric and aceto-acetic acids in the blood, so that the sum of their molecular concentrations should be constant. However, calculation in the present case shows that this was not quite true, the value being 0·039 before treatment and 0·034 five hours later; in other words, the plasma bicarbonate did not rise as much as would be expected, considering the fall in blood ketones. Again, the ammonia index rose (as already mentioned), which suggests that ammonia was produced in default of metabolic bases to help the excretion.

CASE 5.—Male, aged 29, who had had symptoms of diabetes for nine months. The data as regards the effect of insulin on the blood-sugar and ketosis are shown in Table II. On June 11th there was a moderate degree of ketosis. The fall in plasma bicarbonate was roughly equivalent to the increase in the acids of the blood, since the sum of the two was 0·0365, which is about the upper limit of the normal plasma bicarbonate. Considering the low concentration of ketones in the blood, their excretion by the kidney was satisfactory. With the exception of the period from 2 to 4 P.M. it fell parallel to the blood ketones. The patient was given one dose of 10 units of insulin a day, from June 11th, and a week later the analyses of blood and urine after insulin were repeated. The blood ketones had fallen to 0·0024 per cent. and the hourly excretion of ketones was only 0·03 g. After insulin the blood ketones and ketones excreted in the urine were still lower.

The Effect of a Single Large Dose of Insulin.

The following case shows the effect of a single large dose of insulin:—

CASE 6.—Female, aged 28 years, suffered from thirst in May, 1922. She was admitted to Guy's Hospital in January, 1923, with diabetes. She complained of cramps in the calves and feet, and had extensor plantar reflexes. The sugar disappeared from the urine after two days' fast, but reappeared on taking a diet of 5 per cent. vegetables, protein, and fat.

She was readmitted for insulin treatment. On a diet of 5 per cent. vegetables, protein, and fat for a week, she passed daily a very constant amount of sugar—on the average 127 g. The blood-sugar was 0·42 per cent. On fasting for two days the sugar vanished from the urine (see Fig. 1), and the blood-sugar fell to 0·125 per cent. at the end of the fast. She was then given a diet of vegetables, protein, and fat in gradually increasing quantities, and the amount of sugar in the urine gradually increased as shown

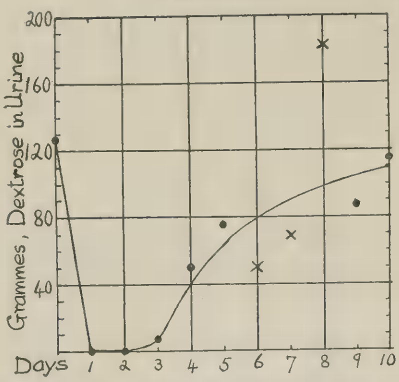
* After lunch, at 9.30 A.M.

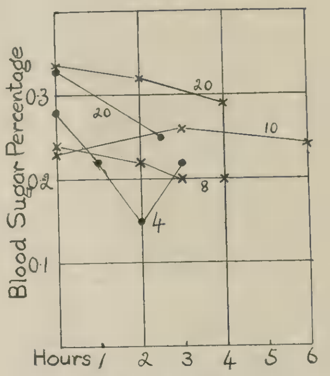
by the curve. On the sixth day (the fourth day after the fast) insulin was given, but owing to a mistake 100 units were injected instead of 10. The mistake was realised immediately, and the patient was given 50 g. dextrose, and 4 oz. bread by the mouth, so that she received in all 110 g. carbohydrate. This treatment was successful in preventing hypoglycæmia from the large dose of insulin, since the blood sugar, which was 0·28 before the insulin, was 0·285 two hours later, and 0·24 the next morning (20 hours later). She felt very hot and sweated, but we would lay emphasis on the fact that these so-called hypoglycæmic symptoms are not necessarily due to hypoglycæmia in the usual sense of the word. Case 1, for instance, noticed frequent hot flushes and sweating ever since the beginning of his treatment, even though the blood-sugar was still high. In fact, hypoglycæmic symptoms arise when the blood-sugar falls below the percentage to which the body is accustomed for the time being, so that they may be felt when the blood-sugar is normal or even higher than normal.

FIG. 1.



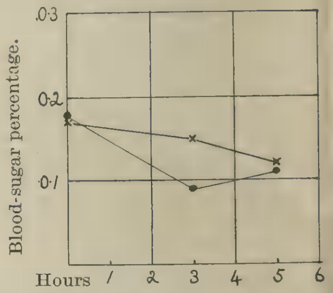
CASE 6.—Sugar in urine. Patient fasted the first two days. Insulin (100 units) administered on sixth day, immediately followed by intake of 110 g. carbohydrate.

FIG. 2.



CASE 1.—Blood-sugar immediately before and after injection of insulin. The numbers in the diagram refer to the numbers of insulin units employed.

FIG. 3.



CASE 8.—Blood-sugar immediately before and after injection of insulin (10 units).

The black dots indicate determination carried out shortly after a period of fasting, and the sign (×) indicates determination on an adequate diet.

As will be seen from the curve, the amount of sugar excreted was diminished on the sixth day when insulin was given, and on the seventh day; but on the eighth day the excretion suddenly rose to 182 g. (blood-sugar 0·43 per cent.), but fell back again on the ninth and tenth days. The curve in the figure has been drawn to represent what the excretion of dextrose would have been if no insulin had been given on the reasonable assumption that the insulin was alone responsible for the irregularities on the sixth, seventh, and eighth days (marked in the figure by crosses), and that the sugar output was otherwise gradually increasing after the fast to the previous level.

Inspection of this diagram gives us information of interest as to the action of insulin. It has been suggested by Kellaway and Hughes[9] from experiments on normal subjects that insulin may cause sugar to be built up into some fat-like complex, containing considerably less oxygen than carbohydrate. Now if this building-up process occurs in diabetes it might perhaps be supposed that after the action of the insulin was over (if only one dose were given) this complex would break down again into sugar which would be entirely excreted. Our observations provide evidence that storage of at least part of the sugar in some form took place.

The evidence is as follows. On the first two days showing the effect of the insulin (sixth and seventh days in Fig. 1) there were 50 g. less sugar excreted than would have occurred if no insulin had been given. In addition, 110 g. of carbohydrate were ingested in the form of glucose and bread on the sixth day. Consequently at the end of the seventh day the body contained 160 g. of extra carbohydrate owing to the insulin. On the third day the blood-sugar rose, and 85 g. of the extra dextrose were excreted. After this the excretion was normal. Consequently 85 g. of dextrose were retained for two days in the tissues, but not in the blood, and may well have been elaborated temporarily into some complex which broke down again into dextrose, when the effect of the insulin had worn off. However, 75 g. of dextrose remains unaccounted for, and it is difficult to avoid the conclusion that it was burnt, because it apparently disappeared completely.

Variations in Effect of Insulin on Level of Blood-sugar.

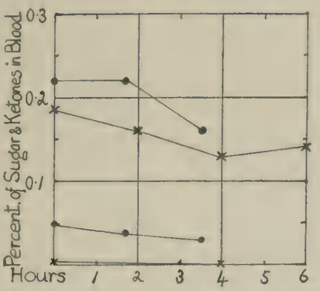
The amount of insulin required to produce a given fall in blood-sugar varies greatly in different patients. We have, however, found a considerable variation at different times in the same case, in the sense that a dose of insulin produces a much bigger fall in blood-sugar at the beginning of treatment than it does later on.

Case 7, seen with Dr. G. L. Cutts, was a man aged 29, who had had diabetes for one and a half years. The urine became sugar-free after three days' fasting. He was then given a diet of vegetables, protein, and fat (calorie value increasing from 1200 to 1500), and on the day after fasting with blood-sugar, 0·32 per cent., he was given an injection of 10 units of insulin, and this was repeated each day following. The blood-sugar was estimated four hours later on several days. The urine became sugar-free after the first two injections. After the second injection the blood-sugar was 0·12 per cent., and after the sixth injection 0·22 per cent.; and a similar value was obtained two days later after the eighth injection. The effectiveness of insulin in reducing the blood-sugar apparently diminished quite soon after the treatment had begun. This patient had suffered from boils for over two months, and these completely disappeared in eight days from the beginning of the insulin treatment.

Similarly, in Case 3, we obtained a fall from 0·27 to 0·12 after the first injection of insulin (10 units), but later on values of 0·18 and 0·21 per cent. were obtained three hours and five hours respectively after injecting twice as much insulin as before. Case 1 was a good instance of this variability (see Fig. 2). The insulin was always given at 11.45 A.M., just before the mid-day meal. The blood-sugar was determined just beforehand and at varying intervals afterwards. The patient had fasted for three days and then had an increasing diet of vegetables, protein, and fat. On the fourth day, after the end of the fast, while the calorie value of the diet was 1540, the first dose of insulin—viz., 4 units—was given. There was a marked fall of 0·13 per cent. in the blood-sugar in two hours. On the next day, with 8 units, the fall was less—viz., 0·04 per cent.—and it took place more slowly. One month later 10 units were given, and this was not sufficient to prevent the rise of blood sugar due to the meal. The patient had gained 9 lb. in weight by this time.

We have similar results (also shown in Fig. 2) when 20 units of insulin were given to this patient, one of them on April 19th just before, and the other on April 21st just after, a one day's fast. In the latter case a fall of 0·08 per cent. in the blood-sugar was noticed, and in the former case the fall was only 0·045, and also took place more slowly. A very similar result was obtained in Case 8 (see Fig. 3), a man of 18, whose symptoms of diabetes were first noticed 15 months earlier. The first dose of insulin was given on the fourth day, after a two and a half days' fast. There was a fall of 0·09 per cent. in the blood-sugar. He was treated with 10 units each day at noon, and 37 days later, after he had gained 1 lb. in weight only, the observations were repeated. The fall in blood-sugar was only 0·05, and it took place more slowly. The diet consisted of vegetables, protein, and fat. The calorie value was approximately 25 per kilo, and the protein 1 g. per kilo. After the fast the diet was gradually increased up to this level, which was reached on the fourth day.

FIG. 4.



CASE 5.—Sugar (upper two curves) and ketones as acetone (lower two curves) in blood, after 10 units insulin.

Our first thought was that the variable response to insulin might be associated with the ketosis. It was possible that when the ketosis was marked at the beginning of treatment, the effect of insulin might be greater than later on when it had practically disappeared. Certainly in Case 1 there was a marked difference between the ketosis on the first and second days of insulin treatment, for on the first day 26 g. of ketones were excreted, and on the second day only 3·9 g. This view was tested in Case 5 (see Fig. 4) and found not to be correct. On June 11th 10 units of insulin, given just before the mid-day meal, caused a fall of 0·06 per cent. in the blood-sugar, when the blood contained 0·05 per cent. ketones, while on June 18th the same dose of insulin caused a fall of 0·056, which was practically the same as before, while on this occasion the blood only contained 0·0024 per cent. ketones. The diet of the patient was constant and contained carbohydrate, only in the form of vegetables and cream.

Another explanation of the apparent diminution in the effect of insulin is to be sought in the state of nutrition of the individual. In Case 3, when insulin was first given, the patient had not long before completed a period of three days' fasting, while in April, a month later, when the 10 units of insulin were given, the patient's nutrition had greatly improved, since he had gained 9 lb. in weight. We have already in this paper provided some evidence, which agrees with the work of others, that one action of insulin is to facilitate the storage of dextrose in the tissues in some form. This storage would more readily take place if the tissues had been depleted of dextrose by previous fasting. Further, as the nutrition of the patient improved, the depôts for the storage of carbohydrate in the tissues would be filled up, so that there would not be the same tendency for dextrose to be absorbed out of the blood-stream by the action of insulin.

It might, of course, be argued that the patient had become definitely worse under our treatment—i.e., that he had lost tolerance for sugar so that insulin became less effective; but against this view was the result of a single day's fast in Case 1, since a greatly increased fall in the blood-sugar was observed with 20 units of insulin on the following day. It is more likely that the carbohydrate depôts became temporarily less full, so that the insulin was more effective. We must at present regard it as rather an open question whether by keeping the depôts more or less empty by constant under-feeding, any curative action of insulin is possible in severe cases of diabetes, as Graham and Harris [13] have suggested.* The calorie value of the diet of our patients was not high considering that they were walking about. They always said they felt hungry, and it would have meant a great deprivation if we had diminished the amount of food still more, so as to prevent their gaining weight, though we might have increased the effectiveness of the insulin by this means. As it was, in Case 1 we increased the amount of insulin instead of reducing the amount of food.

Methods of Administration of Insulin.

We have tried the effect of modifying the administration of insulin. In addition to the results detailed below, we obtained a little evidence that absorption may take place after injection into the maxillary antrum in Case 1. Mr. T. B. Layton kindly carried out this operation for us under local anæsthesia. It is also possible that some absorption occurred after administration by means of a duodenal tube in Case 1. The tube was located by means of X rays.

Administration by Mouth.—It has been suggested that destruction of insulin in the stomach by pepsin might be avoided by giving alkali. Consequently the following procedure was adopted. One drachm of sodium bicarbonate in 5 oz. of water were first given to Case 1, then the usual dose of 25 units of insulin with 1 drachm of sodium bicarbonate in 5 oz. of water, and in five minutes' time ½ a drachm of sodium bicarbonate in 3 oz. of water. The blood-sugar beforehand was 0·19 per cent. (see Table III.); three hours later 0·23; and five hours later 0·25. A control experiment was carried out by observing the blood-sugar at the same hour of the day when no insulin had been administered by any route. The blood-sugar rose steadily from 0·13 to 0·19 after five hours, which was just the same rise as was observed when the insulin was given by mouth.

Administration by Rectum.—The following case presents an example of the effect of rectal administration.

CASE 9.—Male, aged 30, was admitted under one of us in December, 1920, in a semi-comatose state.[4] The urine became sugar-free and the ketosis had practically disappeared on discharge. He was readmitted under Dr. Beddard in April, 1922, passing sugar (blood-sugar 0·4 per cent.), but became sugar-free with dietetic treatment. The effect of rectal and subcutaneous administration was tried just before his dinner, which consisted of vegetables, protein, and fat, but which also contained 1½ oz. bread (see Table III.). On May 3rd, after subcutaneous injection, the blood-sugar remained about the same, the effect of the insulin being neutralised by the bread. On the 23rd bread was given without insulin and the blood-sugar rose from 0·16 to 0·255 in three hours, but no sugar was excreted; while on the 8th when insulin was given per rectum before a similar meal containing bread, the blood-sugar rose from 0·21 to 0·31, which was practically the same rise as when no insulin was given at all. The urine on the latter occasion contained 0·8 per cent. of sugar. Hence it appears that insulin produced no effect when administered per rectum in this case.

Administration of Gum-insulin.—An attempt to reduce the number of injections per day was made by giving the insulin in a vehicle which was only slowly absorbed by the tissues. We made a solution of insulin in a 20 per cent. solution of gum-arabic for the purpose.

(1) By such means a rabbit was given three times the dose of insulin usually required to send it into convulsions. The rabbit did not go into convulsions,

---

* Since the above was written we have heard of three patients who have noticed reactions with doses of insulin that had previously not produced any reaction, and in certain other cases the blood-sugar tolerance curve has been found to improve after a course of insulin of about a month's duration. All these patients were taking a diet that satisfied them, though it contained no carbohydrate other than that in the form of green vegetables.

but about seven hours' later was not quite normal. It recovered and was quite normal next day. The blood-sugar before insulin was 0·13 per cent., and fell to 0·065 per cent. after three hours. On two previous occasions the blood-sugar fell to 0·045 and 0·05, when about one-third the present dose was given without gum.

(2) Case 6 had symptoms of hypoglycæmia when 30 units of insulin were given daily in three injections of 10 units each. She was given 30 units in 20 per cent. gum before her breakfast. She had only slight symptoms of hypoglycæmia three hours later, and these lasted two hours, when her blood-sugar was found to be 0·08 per cent. Twelve hours later she had an attack of urticaria, but there was no local reaction at the site of injection.

These results show a distinct slowing of the rate of absorption of insulin due to the gum.

Respiratory Exchange.

Banting and his colleagues[2] found that the respiratory quotient (R.Q.) in depancreatised dogs rose after sugar and insulin, while the glycogen in the liver was increased. Kellaway and Hughes[9] found in the case of a normal subject, who had fasted for 15 hours, that after insulin there was a rise in the R.Q., with increased output of CO_2. The oxygen intake was once slightly diminished, and in a second experiment slightly increased. Dudley, Laidlaw, Trevan, and Boock[14] found that normal animals under the influence of insulin showed a transient rise in R.Q., but the O_2 intake and the CO_2 output fell continuously, and at the end the liver contained less glycogen than normal. Meakins and his colleagues[3] found that the R.Q. rose to some extent after glycogen and insulin, though the oxygen intake, as judged by the calorie values given, probably fell.

Case 1 seemed to us to be a specially suitable case for studying the respiratory exchange owing to the very large amounts of insulin he was having. Douglas and Haldane's closed circuit apparatus[15] was used, the expired air being analysed for its CO_2 content as suggested by Krogh.[16] The pulmonary ventilation was recorded by placing the rubber balloon in a jar and connecting the latter with a Krogh's recording spirometer. The volume of CO_2 expired was calculated from the CO_2 in the expired air and the pulmonary ventilation.

The first three observations (see Table IV.) were carried out when the patient was having 75 units of insulin a day in equal doses at 6 A.M., 12 noon, and 6 P.M. The patient had his usual breakfast consisting of two eggs, 2 oz. of bacon, 1 oz. cream, and cooked greens at 6.30 A.M. He rested on a couch in the respiration room for about three-quarters of an hour before the experiment. The first and second experiments were carried out at 9.30 A.M., three and a half hours after the insulin had been administered, and the third at 12 noon, six hours after the insulin. In the third experiment the patient had had his lunch, consisting of 2 oz. cheese, two bran and agar cakes, and 1 oz. butter at 9.30 A.M. Very high respiratory quotients, over unity, were obtained in the first two experiments, while the value in the second was 0·98. At this stage we do not wish to lay any stress on our finding, that the R.Q.'s were actually above unity, but only that they were uniformly high. The blood-sugar varied from 0·155 per cent. four hours after the insulin to 0·20 per cent. five hours afterwards.

The last three experiments were carried out under similar conditions, with the exception that the last dose of insulin had been taken 23½ hours before the first experiment. The results offer a great contrast to the first three experiments, the R.Q. varying from 0·84 to 0·86. The CO_2 output was approximately the same, while the O_2 intake was considerably greater. The blood-sugar was 0·32 on July 10th and 0·26 on July 11th. Immediately after the completion of the experiments insulin was recommenced, and on July 12th, at 10.50 A.M., the blood-sugar had fallen to 0·155.

It is possible that there is a difference between the action of insulin in normal and diabetic organisms, but we think that in the latter insulin certainly causes a rise of R.Q. and a diminution in the intake of oxygen.

Dale[11] has suggested a very simple explanation of these facts—viz., that with insulin carbohydrate is oxidised in place of other foodstuffs. This seems a satisfactory hypothesis, but it cannot be the whole truth, as we have already shown that some sugar may be stored for a while. The problem is—in what form is it stored? Kellaway and Hughes[9] suggested some fat complex, because the high R.Q. was associated with a diminished oxygen intake, and if our R.Q.'s above unity are substantiated, there would seem to be no other possible explanation. But for the present we would suggest that the storage takes place chiefly as glycogen, and we would explain the low oxygen intake with insulin on the lines of Dale's hypothesis as follows: After stopping insulin in our case the oxidation of protein and fat takes the place of carbohydrate; but the specific dynamic action of these substances is greater than that of carbohydrate, and so the oxygen intake is increased. When our respiratory experiments with insulin were being carried out, it is unlikely that storage of glycogen was occurring, as the patient had been under treatment so long that all the depôts would be full. However, when the insulin was stopped, the converse process probably took place, and the hyperglycæmia arose partly from the escape of dextrose from the depôts and partly from the food.

In conclusion, we should like to thank the Medical Research Council and the Parsons Research Fund for financial assistance and for providing pancreas when we were ourselves preparing insulin. We should also like to thank various members of the staff of Guy's Hospital for facilities for investigating cases under their care, and the nursing staff for their willing coöperation.

Summary.

1. The treatment over a period of 108 days of a severe case of diabetes, requiring 75 units of insulin a day, is described.

2. Figures are given illustrating the effect of insulin in diminishing ketosis in diabetes and diabetic coma.

3. Insulin had no effect when given by mouth mixed with sodium bicarbonate or by rectum. When mixed with gum and injected subcutaneously, the absorption was a little delayed and a larger dose was tolerated.

4. Evidence, arising out of the administration of a very large dose of insulin, showed that it causes storage of carbohydrate in some form. When the depôts are full, insulin does not have such a big effect in lowering the blood-sugar. The marked rise in R.Q. with insulin is explained on Dale's hypothesis that insulin also causes carbohydrate to be burned in preference to other foodstuffs, and the fall in oxygen intake is explained by the low specific dynamic action of carbohydrate.

THE SILHOUETTE RADIOGRAM.

BY A. P. BERTWISTLE, M.B., CH.B. LEEDS,
RESIDENT SURGICAL OFFICER, GENERAL INFIRMARY, LEEDS.

IN a recent paper entitled "X Ray Prints: A Suggestion,"[1] I endeavoured to show that a display of the outline of the soft parts in X ray prints would not only enhance their instructional value, but would form a more complete clinical record. After trying various methods with this object in view, I have found the following simple process eminently satisfactory. I scratch the X ray negative with a pin, carefully following the skin outline. I then make a print (Fig. 2) and block out the background with Indian ink. Most negatives show a well-defined skin outline.

1

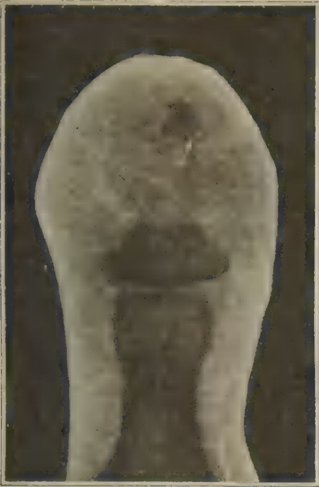

FIG. 1.—Caries of thumb. Note (1) Bone: disorganisation of distal part of terminal phalanx, with abscess cavity in which is sequestrum; and (2) Skin: bulbous end, the result of periosteal whitlow.

2

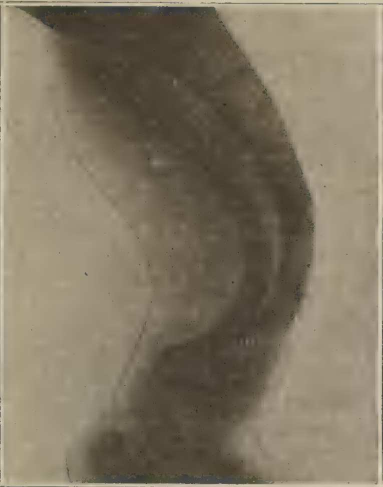

FIG. 2.—Rickets, showing characteristic contour and acompanying bony lesion. (Stage 1 of method.)

3

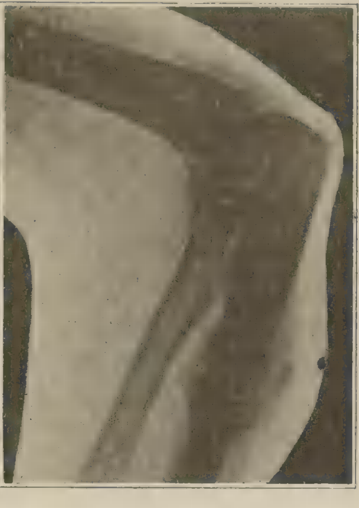

FIG. 3.—Callus of ulna.

4

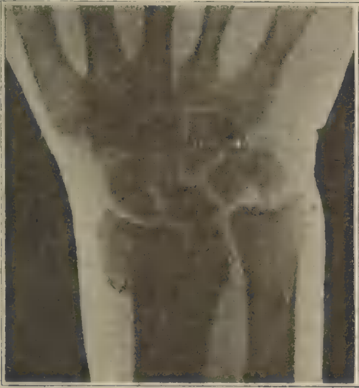

FIG. 4.—Colles' fracture. Note (1) Bone: impaction of radius so that styloids of radius and ulna are on the same level: and (2) Skin: radial deviation.

5

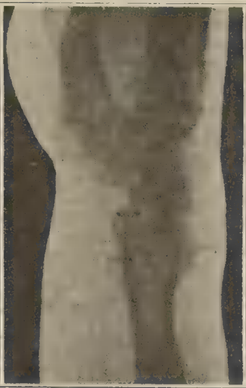

FIG. 5.—Normal wrist-joint.

6

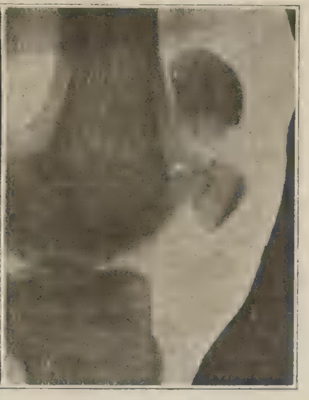

FIG. 6.—Fracture of patella. Note (1) Bone: transverse fracture due to muscular effort, and upward tilting of lower fragment: (2) Skin: swelling of joint and depression over site of fracture.

I have further applied this idea to demonstrate the congenital absence of muscles,[2] muscular wasting, the result of bony disease, as in a tuberculous knee, and the relationship of external sinuses to surrounding tissues, the sinus being previously injected with bismuth. Tuberculous dactylitis, periosteal whitlow (Fig. 1), osteitis deformans and rickets (Fig. 2) all show the characteristic contour as well as the accompanying bony lesion. In the case of fractured ulna (Fig. 3) the illustration given shows the relationship of the callus to the surrounding parts, and one is able to assess to what extent the swelling is due to the bone condition, and to what degree to surrounding tissue damage.

The skin outline is instructive in cases of dislocated shoulder, where increased axillary girth (Callaway) and flattening are characteristic features. In cases of Colles' fracture the radial deviation (Fig. 4) and "dinner-fork" deformity are clearly defined. A normal wrist-joint appears in Fig. 5. In fractured patella (Fig. 6) the groove between the fragments is quite obvious.

The actual result is a silhouette skiagram, a combination which has the properties of an X ray plate and a clean cut silhouette, displaying the deformity or otherwise of the soft parts. The ordinary radiogram is largely a silhouette of bone; this is one of bone and flesh. The advantages this has over an ordinary radiogram are: (1) a more striking clinical picture, often rendering a photograph unnecessary; (2) the ease with which it may be obtained; (3) the position in which the limb is photographed is indicated; and (4) the cause of the whole deformity may be analysed at a glance.

I am indebted to Dr. H. B. Scargill and the radiological staff of the General Infirmary at Leeds for the preparation of the prints.

RESULTS OF THE SCHICK METHOD

APPLIED TO A FEVER HOSPITAL STAFF.*

BY B. A. PETERS, M.D., B.C. CAMB., D.P.H.,
MEDICAL OFFICER, HAM GREEN HOSPITAL AND SANATORIUM, BRISTOL; LECTURER IN INFECTIOUS DISEASE, UNIVERSITY OF BRISTOL.

DURING the last 18 months all members of the staff of the Bristol City Fever Hospital, Ham Green, have been tested by the Schick method. In half the cases the test toxin was diluted immediately before use. In the other half toxin as diluted by the makers was employed. There appeared to be no appreciable difference in the results, and the makers state that they have found no alteration in the toxic strength through material travelling by post. While many of the results are very distinctly positive or negative, a considerable number of borderland cases arise (at least in adults) in which it is very difficult to decide in which category to include them. Such cases have been called positive in our results. One series of 11 were tested simultaneously with material from different firms on the same day on the same arm. The results with the material from firm A (which was used in all the other patients) were 8 positives and 3 negatives, and with material from firm B, 5 positives and 6 negatives—an alarming disparity.

Results.

In all 212 were tested; 85, or 40 per cent., gave a positive or pseudo-positive reaction, and all these were given two or three doses of toxin antitoxin mixture. They were not allowed in the diphtheria wards until six weeks after the last dose, by which time a fair measure of immunity is stated to have developed. As a counsel of perfection they should be re-tested before contact with diphtheria, but there is a limit to these procedures beyond which it is not wise to press the forbearance of the new staff, as they are all also vaccinated, and some inoculated with T.A.B. vaccine and on occasion with *B. pestis* vaccine! Amongst those who had previous attacks of diphtheria, 18 gave a negative test (one of these had diphtheria twice) and 6 a positive test (one of these had also had two attacks within three years). Amongst the older members of the staff who had been in contact with diphtheria for periods varying from a few months to five and a half years without contracting the disease, 7 gave positive reactions varying from slight to very strong. Amongst those giving negative tests, two developed clinically follicular tonsillitis with a profuse growth of diphtheria bacilli in culture, and three developed a definite clinical attack of diphtheria, including myself, who contracted the disease after 14 years' daily contact with it, and a ward sister who had had eight years' fever nursing. The organism from my own throat killed a guinea-pig in 36 hours and was thus unusually virulent. Amongst those inoculated with toxin antitoxin mixture, two developed diphtheria while being immunised (not then being in contact with known cases of diphtheria), and one two months after completion of immunising course. Therefore 8 in all contracted diphtheria in 18 months—i.e., at the rate of 5 per annum. The numbers attacked in the previous 12 years were, from 1921 backwards: 12, 12, 6, 6, 2, 3, 2, 1, 2, 7, 6, 5—i.e., an average of 5 per annum.

During the period of these observations the incidence of scarlet fever attacks in the same patients is of interest. Out of 127 with negative Schick tests, 5, or 4 per cent., contracted scarlet fever; of the 85 positives 10, or 12 per cent., contracted scarlet fever. This suggests some relationship in the susceptibility to the two diseases and is in accord with the well-known fact that those suffering from scarlet fever are highly susceptible to diphtheria and vice versa, although the numbers are much too small to dogmatise upon. Our results here suggest that the claims for these methods are decidedly exaggerated in the presence of heavy and repeated doses of a virulent type of infection, such as was present in this area during most of the time in which these observations were made.

Conclusions.

Our experience here would suggest: (1) That a negative Schick test does not necessarily indicate clinically immunity to the disease; (2) that a positive Schick does not always indicate a high susceptibility to the disease; (3) that the effects of immunisation do not always prevent the disease. This is in accord with clinical experience, as one has frequently seen second attacks of the disease in the same person. Probably some people give a bad immunising response to infection, and one would not expect any artificial method to give a better immunity than does an actual attack of a disease. No one would claim that vaccination is a better protection against small-pox than an attack of small-pox.

These methods are undoubtedly of considerable value in protecting against the disease, but immunity against any disease can never be absolute, as it must depend on the virulence and size of dose of the infection and the general condition of the patient at the time of infection. Presumably, amongst those exposed to slight and occasional risks of infection, the immunity conferred would be better than under the concentrated fire to which fever hospital staffs are exposed. I think that for these persons it would be better to abolish the test and give them all two or three doses of toxin antitoxin mixture. However, this has the disadvantage of sensitising them to horse serum if they should consequently develop the disease; also the reactions produced by the mixture are sometimes decidedly severe. It would be better for the success of this method that the dogmatic statements claiming its absolute protection should be combated; otherwise occasional disappointment will ensue, followed by the falling into disrepute of the whole procedure. My experience suggests that the method, while constituting a valuable weapon in the combating of diphtheria, has distinct limitations.

I am indebted to Dr. J. A. Nixon for instructing me in the technique of this test and for carrying out some of the earlier tests.

PREGNANCY COMPLICATING FIBROIDS IN A PRIMIPARA AGED FORTY-SIX YEARS.

BY A. LOUISE McILROY, M.D.,
D.SC. GLASG.

(*From the Obstetrical and Gynæcological Unit, Royal Free Hospital.*)

IT has been found that the occurrence of pregnanc in a patient the subject of fibroids of the uterus i rarely associated with any disastrous effects, excep where degenerative changes take place in the tumou substance, or where torsion of the pedicle ma accidentally happen. The general rule adopted b most gynæcologists is to refrain from operativ interference during the course of the pregnanc unless there is some urgent reason for doing s If obstruction to labour appears to be inevitab it is advisable to allow the pregnancy to continu to full term, and to deal with the fibroids aft Cæsarean section has been performed. Fibroids a seldom found to be a direct source of post-partu hæmorrhage.

Investigations into the causation of these tumou has led me to believe that they constitute one of t chain of symptoms associated with toxæmia, havin in the majority of cases its source of infection in t mouth and intestinal canal. Hæmorrhage in no pregnant cases is due not to mechanical irritation of the uterine mucosa alone, but to a congestion of the tissues under the influence of a chemical toxin. The uterus is endeavouring to eliminate the poisonous products from the intestine as it is a channel of excretion under normal conditions.

---

* A paper read before the West of England Branch of the Society of Medical Officers of Health on June 20th, 1923.

If cases of fibroids are carefully investigated it will be found that there is evidence of toxæmia in the majority of them; this toxæmia is not always consequent upon degenerative changes in the tumours themselves, but rather points to some influence in their origin. The notes of the following case may be of interest owing to the problems involved in the accurate diagnosis of pregnancy and its treatment.

The patient, aged 46, married three years, sterile, had regular menstrual periods until Nov. 8th, 1922, when they ceased. Some weeks later she noticed a swelling in the right iliac region, and consulted her doctor about the middle of December. A diagnosis of fibroids of the uterus was made, and the amenorrhœa was looked upon as a symptom of the onset of the menopause. She was sent up to me for examination and treatment.

Condition on Examination.—When I saw the patient the tumour in the abdomen was easily palpable, tender, and freely movable. The uterus was involved in a mass of fibroid tumours confined mainly to the pelvic area. As there was some softening of a portion of the swelling I hesitated to exclude the possibility of pregnancy, although there were no breast changes present. There was a history of slight sickness, but as the patient showed some evidence of toxæmia it could not be taken as a reliable sign of pregnancy.

I wrote to the doctor explaining my difficulty of diagnosis and asking him to let me see the patient in a few weeks' time. She was admitted to the gynæcological department on Feb. 12th and again examined. The tumour was found to be larger and more tender, and the pelvic mass was also enlarged. There was slight secretion in the left breast, but no definite areola seen. Under anæsthesia a portion of the pelvic mass felt softened like a pregnant uterus, although it was still somewhat difficult to make an accurate diagnosis. The patient complained of pain in the large tumour, and showed evidence of the presence of toxæmia. For this reason I decided to operate, but did not promise to do a hysterectomy, although the patient was anxious not to continue the pregnancy owing to its possible complications.

Operation.—On Feb. 20th the large tumour was easily removed, being pedunculated; it was found to be undergoing necrobiotic degeneration on subsequent incision. The uterus was enlarged and softened to about the size of 12 weeks' pregnancy, and its walls were studded with about a dozen fibroids of varying sizes. Two of the largest of these felt softened and were dissected out from the uterine wall. Although there was considerable hæmorrhage on enucleation of the tumours, and although the uterus was so much involved, I decided to leave the condition alone. The pelvis showed considerable contraction in its antero-posterior diameter.

Course of Case.—There was no interruption of the pregnancy after the operation, and the patient left the hospital well on the twenty-second day. Owing to the patient's age, to the degree of pelvic contraction, and to her now expressed desire to go to full term, she was advised to return for Cæsarean section. Her general condition throughout the remainder of the pregnancy was very much improved. On August 7th she was admitted to the obstetrical department, and next day I performed Cæsarean section before the onset of labour. The placenta was situated on the anterior uterine wall, and there was considerable hæmorrhage from the incision, but the operation was otherwise uncomplicated. Another tumour was excised, but the uterus was not removed as it was thought possible that the tumours would involute. The child was perfectly healthy and weighed 7 lb. 2 oz. at birth. The patient left hospital well on Sept. 3rd, the uterus on examination showing a marked diminution in the size of the tumours.

The interest of the case lies in the occurrence of pregnancy in an elderly primipara with numerous fibroids, and the difficulty of a definite diagnosis in the early weeks. Cæsarean section was indicated on account of the contracted pelvis and the possibility of injury to or obstruction by the tumours in the course of labour, together with the facility for hysterectomy if deemed necessary. The case is one more example of the beneficial results of conservative obstetrics even in the presence of several indications for more radical measures.

Clinical and Laboratory Notes.

A NOTE ON JAW-WINKING.

By J. ALEXANDER WILSON, M.D. GLASG.

JAW-WINKING is the inelegant term applied to involuntary movements of one or both eyelids that are occasionally associated with movements of the jaw, as in chewing, speaking, or crying. The ætiology of the condition is obscure. Sometimes it is congenital, when it has been called an "atavistic anomaly." Another theory assumes that the "levator palpebrarum, ordinarily supplied by the third nerve, receives in these cases an additional supply from the fifth nerve, which also innervates the muscles of mastication." It is frequently associated with ptosis, or there may be ptosis in one eye and jaw-winking movements in the other.

I have observed a child, obviously a case of ptosis, who was admitted to hospital for operation, crying vigorously whilst it was being prepared for operation. As it cried I observed that the ptosis had disappeared; the lid was drawn right up, exposing the white sclerotic above the cornea. When the child ceased to cry the lid drooped again. Here we have a condition of paralysis alternating with extreme contraction. One case was reported to have followed injury to the child's head—"skull dented in"—and another as being associated with "paresis of the left side of face and body."

The following case is worthy of record:—

The patient is a man aged 50. When he is not speaking or eating his eyes seem exactly alike. The vision in each is good. When he speaks the right upper eyelid falls and covers the eyeball, and when he stops speaking the eyelid is raised into its normal position. When he speaks suddenly or energetically the fall of the lid seems of greater range and is more obvious. When he speaks quietly or languidly the range of movement is less and the abnormality is less obvious. The lid also droops when he eats.

This is an ordinary case of jaw-winking, but the interesting point is its ætiology. Twenty years ago this man was in a railway collision and suffered from shock which kept him in bed for several weeks. He had no obvious injury. Shortly thereafter he noticed this peculiarity of his right eye. He is an intelligent business man, and I have no hesitation in accepting his statement that the collision was in some way responsible for the disordered muscle activity. If this ætiology is accepted the case is interesting from a medico-legal point of view.

In all cases of jaw-winking a voluntary impulse from the cortex cerebri to the fifth nerve initiates an involuntary impulse in a section of the third nerve. In my case, probably, there has been a lesion or displacement of an upper neuron, permitting shunting, or escape of impulse, from the line of the fifth nerve, on to that of the third nerve.

Cambuslang, Glasgow.

A CASE OF
DIPHTHERIA OF THE BIG TOE.

By E. EMRYS-ROBERTS, M.D.,

PROFESSOR OF PATHOLOGY AND BACTERIOLOGY, WELSH NATIONAL SCHOOL OF MEDICINE.

THE following case-record presents certain points of interest in diagnosis and treatment:—

The patient, a youth aged 22, who enjoyed excellent health, developed a blister at the base of the right big toe after a game of football. When the blister burst the site became ulcerated, and this was quickly followed by swelling of the foot and enlargement of the femoral lymphatic glands. He felt out of sorts and "shivery." In spite of vigorous local treatment the foot remained swollen and the ulcerated area unreduced in size for the succeeding five weeks. Towards the end of this period he began to feel giddy and to suffer from double vision and inability to read. He also about this time began to experience trembling and weakness at the knees, some difficulty in walking, and numbness in hands and feet.

Condition on Examination.—Eight weeks after the receipt of the injury the swelling of the right foot had gone down, but there was present an indolent ulcer on the anterior and outer side of the base of the right hallux, forming a sort of half-collar about one-third of an inch in width, with a slight colourless discharge. Complete analgesia existed over the soles of both feet and over the lower half of each leg posteriorly. There was definite weakness of extension and flexion, especially the latter, at the knee-joints, but no paresis of the muscles operating at the ankle-joints or toes. The right grip was weak and there was some wasting of the muscles of the hand. Definite, but incomplete, analgesia was present over both hands and over the cheeks and nose. All the deep reflexes of both arms were lost, as were also the Achilles jerks. The knee-jerks were feeble and only obtained on reinforcement. Both sixth nerves were affected, and there was limitation of movement and diplopia on attempted lateral deviation of the eyes. He could not see ordinary print, but distance vision was good. The pupils reacted to light, and the discs were normal. Though speech was slightly nasal, there was no regurgitation and no difficulty in swallowing. Furthermore, there was no obvious involvement either of the myocardium or of the respiratory muscles.

Course of Case.—In the absence of any history of sore-throat the polyneuritis was considered to be definitely related to the condition present in the big toe. Both in direct smears and in cultures obtained from the ulcerated area the Klebs-Löffler bacillus was readily identified, and immediate treatment with antitoxin was followed within 48 hours by distinct amelioration of the symptoms. Although the wound was, additionally, heavily infected with *Staphylococcus aureus*, healing started at once and, in a few days, newly-formed epithelium covered the site of the ulcer. During the four months up to the time of writing the improvement has been consistently progressive and now, although there yet remains some wasting and loss of power in the right hand, the patient is practically fully restored to healthy activity. The source of infection has completely eluded detection, in spite of the efforts directed to this end by the patient's father, a medical man.

Although cases of " wound diphtheria " are reported from time to time, the occurrence of a diphtheritic lesion limited to the site of the wound and unrelated to any obvious source of infection is uncommon. Nevertheless, the possibility of this form of diphtheria is to be borne in mind whenever a wound, for no clear reason, betrays a tendency to resist all forms of local treatment, since this obstinacy was essentially, in the case here recorded„ the first indication of infection by the Klebs-Löffler bacillus.

For the history and notes I am indebted to Dr. Alfred Howell, who saw the case in consultation.

Cardiff.

Reviews and Notices of Books.

A SYSTEM OF SURGERY.

Second edition. Edited by C. C. CHOYCE, C.M.G., C.B.E., B.Sc., M.D., F.R.C.S., Director of Surgical Unit, University College Hospital Medical School, Surgeon to University College Hospital, Consulting Surgeon to the Seamen's Hospital, Greenwich. London: Cassell and Company. In three volumes. Pp. 1013, 1056, 1176. £6 the set.

THE second edition of Choyce's excellent " System of Surgery " has been long overdue, owing, as the editor explains in his preface, to the war and its subsequent disturbances. There have been certain changes throughout the course of the work, some of the chapters have been re-written by new authors, and others have been revised. The war was bound to be responsible for certain additions to this edition, but we are glad to see that only the real advances in surgical knowledge and technique have been included. Many methods of great value in war conditions are entirely out of place in civilian work, and the editor has been happy in his choice of what to leave out. Certain chapters have been entirely rewritten; X ray diagnosis now falls to Mr. Magnus Redding, and he has produced a chapter which ranks amongst the finest in the work. He has given us many admirable radiographs, and is well abreast of modern improvements and discusses ably such recent methods as pneumo-peritoneum and ventriculography. Colonel L. W. Harrison contributes an authoritative and lucid chapter on syphilis. Colonel J. W. West has rewritten the chapter on tetanus. In view of the amount of material provided by the late war his article is disappointing. The typical form of tetanus is well described, but its unusual forms are only very briefly dismissed. The chapter on the pharynx, larynx, and ear is rewritten by Mr. Norman Patterson, and gives a description of the diseases of these regions which a general surgeon will find of value. Orthopædic surgery has been taken over by Mr. W. H. Trethowan, and he has effected a great improvement in one of the weaker chapters of the first edition.

There are noticeable changes in arrangement, and the chapter on military surgery is rightly abandoned, for, as the editor points out, military surgery is a branch of its own and requires its own literature. There are two entirely new chapters, one by Prof. C. A. Pannett on simple ulcers, and another by Mr. E. K. Martin on toxæmia, septicæmia, and pyæmia. Mr. W. H. Clayton-Greene adds to his admirable chapter on diseases of the tongue his experiences of the use of diathermy in carcinomata of the mouth and tongue; Mr. C. A. R. Nitch has given an excellent account of gas gangrene; in addition there are added to appropriate chapters descriptions of methods of blood transfusion, the paraffin dressing of burns, the surgical types of splenomegaly, and a fuller discussion of arteriovenous aneurysms,

In places there are but few alterations, and sometimes too few. For instance, in the chapter on the intestines not quite a page is given to diverticulitis under the heading Diverticula of the Colon; later (p. 527) a section on fibromatosis of the colon occurs and is described as a clinical entity, which is said to produce a condition of false diverticula, whereas we now know that chronic diverticulitis is the cause of the fibromatosis. It is impossible to obtain an equal level throughout such a work as this. Overlapping must always occur, and it is not uncommon to find that in the desire to avoid it certain subjects are treated most cursorily; in this book, for example, subphrenic abscess is scurvily treated. Two varieties are mentioned in the chapter on diseases of the stomach as being complications of perforated ulcers. Later on in another chapter the subject is again introduced, but no attempt whatsoever is made to present it as a whole in a lucid fashion, and since Barnard's classification this is hardly excusable.

These, however, are but blemishes, and this " System of Surgery " remains, in our opinion, one of the best text-books of surgery in this country. It is very well printed in large clear type, the illustrations are numerous and excellent, the greater proportion of the microscopic preparations are drawn, not photographed, and the book is well arranged throughout. It covers a wide field, for it appears to be the work of choice among students for the Conjoint Board examination as well as for the Final Fellowship, and indeed may safely be used as a book of reference for any member of the profession settled in surgical or general practice. There are certain articles which in themselves mak the work worth buying. Mr. Wilfred Trotter' chapter on the scalp, skull, and brain contains th most brilliant exposition of intracranial injuries i the English language; not only is his subject matte excellent, but his article is written in such delightfu style that it is a constantly recurring pleasure t read it through. Mr. J. Sherren has supplied tw fine articles, one in Vol. II. on the stomach an duodenum, and the other in Vol. III. on th surgery of nerves, subjects which he has made ver particularly his own. That this second edition wil have a wide welcome we have no doubt.

ASTHMA.

By FRANK COKE, F.R.C.S. Bristol: John Wrigh and Sons, Ltd. 1923. Pp. 260. 15*s.*

To write a book on asthma at the present time is a unenviable task. The prominence rightly given recent years to " sensitisation to foreign proteins, as a factor in the ætiology of asthma, makes it fairly clear what must be the main theme of any work on asthma. However, when we try to go a little deeper into this subject, we are at once involved in uncertainty and controversy.

Mr. Coke speaks somewhat dogmatically on the specificity of hypersensitiveness to particular proteins and compares the results to anaphylaxis; unfortunately, he makes no mention of Storm van Leeuwen's recent work, which suggests that the specificity is by no means so great as is generally believed, and that the vast majority of hypersensitive patients give a marked cutaneous reaction to human dandruff. This divergence of views on a fundamental point illustrates the difficulty of the subject. Undoubtedly the clinical part of the book is far the most satisfactory, for here the author is describing his own experiences. There is an excellent coloured illustration showing types of skin reaction and the technique employed by the author is clearly described. Out of 350 cases of asthma he finds a positive reaction in 52 per cent. This is about the same proportion as that found by Chandler Walker, but is much higher than most people in this country are inclined to admit. The prevention and treatment of asthma is very fully considered, both during the acute attack and in the intervals between them. This takes up rather more than a third of the book. The account is sensible and impartial, and the classification is good. There are one or two small points that may be mentioned. The value of oxygen when given in sufficient quantity by means of an efficient apparatus is not sufficiently emphasised, and we have looked in vain for some reference to the old experiments on treatment with compressed air. No mention is made of tuberculin in the section on non-specific protein therapy, though valuable results have been obtained in cases where there was no evidence of tubercle. The author himself believes firmly in the mixed coliform vaccines of Danysz. The account of the structure of the lung given on p. 71 is not now generally accepted—the truer picture being that which we owe to Miller (*Jour. Morphol.*, xxiv., 449, 1913). The problem of sensitisation to drugs is mentioned. From the theoretical point of view this subject is of great importance, since people may be hypersensitive to substances other than proteins. The hæmoclasic crisis is also described. The references at the end of the chapters show that the author has read widely.

Mr. Coke has given us an interesting and readable book. We note that, but for his untimely death, Dr. A. Latham would have collaborated in the work, and the author hopes that the book will add its small quota in the perpetuation of his memory.

DISEASES OF THE BREAST.

By WILLMOTT H. EVANS, M.D., B.S., B.Sc., F.R.C.S., Consulting Surgeon to the Royal Free Hospital. London: The University of London Press, Ltd. 1923. With 106 illustrations (15 coloured). Pp. 495. 27*s.* 6*d.*

IN publishing a work on the Diseases of the Breast Mr. Willmott Evans enters a field which has already been well tilled, but the success which has attended his enterprise more than justifies it. There is always room for the book which is a record of personal experience; and when, as here, it is enriched by a painstaking and critical study of the literature, its position is immediately established. Mr. Evans treats his subject systematically. The first two chapters deal with anatomy and physiology, and methods of examination. Then, following sections on abnormalities of development, atrophy, and hypertrophy, the inflammatory conditions are described in detail; while the last two-thirds of the volume are devoted to the innocent and malignant neoplasms. The book is clearly written and admirably illustrated by drawings of subjects and naked-eye specimens; microscopic pathology receives less attention. It is thoroughly practical and more space is devoted to treatment than in many text-books.

For the most part the author's views are modern and orthodox, though he differs from accepted teaching in some particulars. He is inclined to ascribe chronic interstitial mastitis to some form of autotoxæmia, and he is a believer in the parasitic theory of the origin of cancer. Again, he advises removal of the supraclavicular glands in the complete operation for carcinoma, though it is generally believed that if these glands are infected the case is practically inoperable, and where possible he dispenses with any form of drainage of the wound. But though the author holds definite views, they represent reasoned and logical opinions and not prejudices. The book is worthy of study, and will appeal to the student and the general practitioner alike.

GONORRHŒA.

By DAVID THOMSON, O.B.E., M.B., D.P.H. With contributions by DAVID LEES, D.S.O., M.D., F.R.C.S.E.; CLAUDE H. MILLS, M.R.C.S., L.R.C.P.; ROBERT THOMSON, M.B., Ch.B.; and KENNETH MACLACHLAN, M.B., Ch.B. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 519. £2 2*s.*

Dr. David Thomson, whose long and painstaking researches into the bacteriology of gonorrhœa are well known, is responsible for the large part of this book dealing with the bacteriology and immunity. He has dealt exhaustively with the subject, and while most of the matter set down has already appeared under his name in medical journals it is convenient to have the whole subject dealt with in one volume. While the bacteriological problems are mainly of interest to workers in laboratories, the clinician will profit from a clear understanding of the issues involved, and will be glad to have the pathological side of the subject fully set out. The rest of the work deals adequately with the anatomy and pathology and treatment of gonorrhœa. Among these chapters, which are all good, we would specially commend that on Infection, Incubation, and Abortive Treatment, by Dr. C. H. Mills. The matter is admirably presented and gives evidence of long experience, soundly observed and recorded. The section by Dr. Lees dealing with the clinical manifestations and practical modern treatment is concisely written and comprehensive.

The volume is well printed and produced.

LESSONS IN PATHOLOGICAL HISTOLOGY.

By GUSTAVE ROUSSY and IVAN BERTRAND. Translated from the Second French edition by JOSEPH MCFARLAND, M.D., Sc.D., Professor of Pathology and Bacteriology, University of Pennsylvania. London: Constable and Co., Ltd. 1923. Pp. 278. 16*s.*

FEW subjects are so difficult to teach and to learn as morbid histology. The morbid anatomist can demonstrate an actual lesion to his class of students with the reasonable certainty that each one of them sees what he himself sees. But in morbid histology the microscope intervenes between the teacher and the taught, and except with the simplest objects there may be the greatest difficulty in arriving at a basis of common understanding. With demonstrating eyepieces and some form of projection apparatus teaching may be rendered less laborious, but these accessories of the class-room cannot help the student in his private reading; he must still puzzle out his microscopic preparations as best he can with the aid of a text-book. In "Lessons in Pathological Histology," by Drs. Roussy and Bertrand, the subject is treated more clearly and satisfactorily than in any text-book with which we are acquainted. The book makes no pretence of being a complete treatise on morbid histology, though it is comprehensive in scope and contains a surprising amount of information. The illustrations are from drawings of microscopic preparations, and though a few of them have suffered somewhat in reproduction, they are well chosen and fulfil their purpose most admirably. In some cases a low-power view of the section is supplemented by a high-power view of one or more portions, and each drawing is labelled very completely. Each figure is accompanied by a page of text describing clearly how the sections should be studied. First the diagnosis of the organ is discussed, then that of the lesion, and the conclusions to be drawn are summed up fairly and accurately.

The general practitioner will find this book a most useful help in the interpretation of such preparations as he may have made from his cases, while to the student who reads with its aid, morbid histology should cease to be what it too often is, an incomprehensible subject in which there is neither beginning nor end. Instead of being tempted to learn a few selected slides by heart, relying on his powers of "spotting" to pull him through in times of stress, he will acquire the habit of regarding a microscopic preparation as a problem to be solved by the ordinary processes of logical reasoning, and he will collect at the same time enough actual knowledge to satisfy all his requirements.

LIFE MOVEMENTS IN PLANTS.

By Sir Jagadis Chunder Bose. Transactions of the Bose Institute. Vols. III. and IV., 1920–1921, pp. 599–902. London and Calcutta: Longmans Green and Co. 1923. 20*s.*

This volume contains a further series of investigations made in the Bose Institute in Calcutta by Sir Chunder Bose and his collaborators into the sensitivity and responses of plant tissues to stimuli. They are notable for the continued use and further elaboration of methods of measurement and record of a wonderful degree of delicacy which might well find applications in other experimental fields. The papers mostly deal with highly technical questions of plant irritability, and the last chapter gives a useful review and summary of the first five volumes of the Transactions of the Institute. There is also a paper of more general interest on methods of control of the water-hyacinth (*Eichornia*), a plant which grows so exuberantly when it gets to a new country that it has become a serious obstruction to navigation, water-supplies, &c., in India as it has in America and Australia.

CHAMBERS'S ENCYCLOPÆDIA.

A Dictionary of Universal Knowledge. New edition. Edited by David Patrick, M.A., LL.D., and William Geddie, M.A., B.Sc. London and Edinburgh: W. R. Chambers. Vol. I., 824 pp.; Vol. II., 840 pp. In ten volumes. £10.

Those of us who learned to read from the bold letters which indicate the scope of each volume of Chambers's Encyclopædia retain for this work an affection which may be said to survive succeeding editions rather than to grow with their issue. The change from the A to BEA, BEA to CATA, on the first and second volumes of the 1888 edition familiar to our childhood, to the A to BEATTY, BEAU to CATA on those of the present edition seems unnecessary and meaningless to our jealous eye, though the prominence given to the name of the gallant admiral whose brief biography ends Vol. I. may be taken as an indication of the efforts made to bring the encyclopædia up to date. It must be admitted that these efforts have been somewhat spasmodic and uneven; for example, the article on boils and that on cataract, which include notes on treatment, appear to have suffered no revision since 1888, while the reader who desires a brief account of modern biochemistry is referred back to an article on animal chemistry which cannot but disappoint him. We need not further discuss the medical articles, however, for it is not to a general encyclopædia that an expert will turn for up-to-date information on his specialty. Subjects connected with or radically altered by the war are well treated. In certain places where articles have been brought well up to date the bibliography has escaped attention. These criticisms having been made, it remains to record the pleasure with which we greet our old friend, rejuvenated, on the whole, skilfully enough. For a moderate price a man who invests in this encyclopædia provides himself with sound information on almost any subject that may interest him, while if he makes full use of cross-references, there is no limit to the knowledge he may acquire with little effort. It is these qualities of simplicity and conciseness that have characterised previous editions of this work and account for their popularity. We anticipate for this edition an even wider public.

FASTING AND UNDERNUTRITION.

By Sergius Morgulis, Professor of Biochemistry, University of Nebraska College of Medicine. New York: E. P. Dutton and Company. 1923. Pp. 407. $5.00.

The experimental study of starvation has long been a favourite method of approaching nutritional problems. In fact, as the author points out, fasting as a method of investigation has been not infrequently used without full appreciation of the phenomena of fasting. We believe that the present volume will find an important place in the literature of nutrition, because it supplies this need for a separate study of the phenomena of inanition. The author's objects have been, in the first place, to collect and classify what is known about the subject, and in the second place to consider these facts in their proper biological setting. The subject is considered from every aspect and the book is divided naturally into five parts, of which the first treats of physiological inanition, as seen in hibernation, metamorphosis, and such special cases as the breeding salmon; the second deals with the chemical, physiological, and morphological phenomena of experimental inanition, acute, partial, chronic, and intermittent; the third part is concerned with the relation between inanition and growth. An introduction and a very valuable bibliography complete this useful volume.

In order to make the book quite complete, the author has introduced chapters on water, oxygen, and vitamin starvation; these special subjects perhaps fall a little outside the proper scope of the work, especially the one on oxygen starvation, which is really superfluous. Otherwise we have nothing but commendation for the author's achievement.

ADVICE TO CONSUMPTIVES.

Recovery Record for Use in Tuberculosis. By Gerald B. Webb, M.D., and Charles T. Ryder, M.D. New York: Paul B. Hoeber, Inc. 1923. Pp. 79 and Tables. $2.00.

This is a most excellent production. No other book, with the exception of Dr. Lawrason Brown's "Rules for Recovery," has yet been published of such value to the tuberculous patient. About half the book consists of chart sheets, enough space being given to allow the patient to record his temperature, pulse, and weight continuously for two years. The very fact that provision has been made for a two-year record must bring conviction to the patient that the duration of his disease is not a matter only of months. Above and below each chart there is a philosophical or instructive quotation. Shakespeare, Ecclesiastes, Dante, Epictetus, Homer, Marshal Foch, and many other sources have been tapped, and Foch's dictum, "I involuntarily turn my back on disaster," is a suitable pendant to Trudeau's famous rule "Conquer Fate by acquiescence." The authors' advice is the product of 25 years' experience, and it is evident that they have spent these years in the study of the patient as well as of the disease. The distinction they draw between idleness and laziness is subtle but happy. "Idleness is merely doing nothing; laziness is doing nothing with contentment and gusto, and whoever achieves this will almost certainly recover." With regard to false recoveries, they quote the famous Irishman who said: "Many an over-confident patient has died cured." Several useful hints are given as to the cultivation of hobbies and avocations, and the patient is told never to stand when he can sit, nor to sit when he can lie down. Many a man has made important advances in the knowledge of his calling, of literature and of truth while confined to his bed or chair, and the authors' chief lesson is that life may be made even fuller than before if the patient adjusts himself to new conditions. "Do not forget that of all the countless remedies proposed, rest alone has stood the test of time." The quotations in support of this teaching are innumerable, and it is sufficient to refer to Trudeau's: "I know I have hurt nobody by rest, but I am quite sure I often have by allowing them to exercise." The authors recommend patients to take fresh air externally, internally, and eternally, and to the patient who worries they suggest that a definite time be set aside in which to get all the worrying done for the day. As for risk of infection, the opinion is expressed that a healthy adult incurs less risk in living with a tuberculous patient than in riding down town in an automobile. One more quotation: "There is no such school of character as tuberculosis bravely met and rightly faced" (Minor).

The reader, who has absorbed the philosophy of this both spirited and spiritual work, is well equipped to meet disaster, whether it come in the guise of tuberculosis or any other disease.

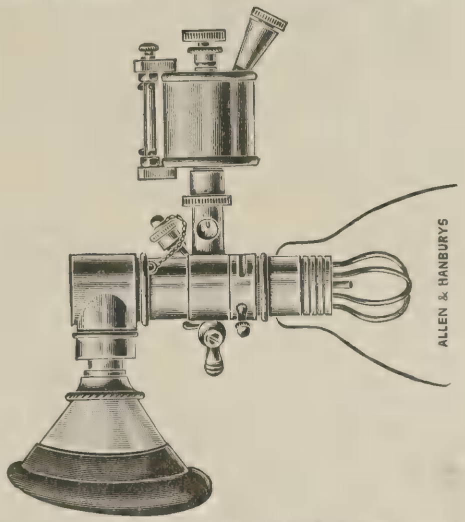
JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XX. July–September.—Dr. G. W. Ronaldson, in his Glasgow M.D. thesis entitled Serum Phenomena and Their Relationship to the Prognosis of Diphtheria, and based on the study of 1000 cases of diphtheria, points out that the prognostic importance of serum phenomena in diphtheria, which was first emphasised by J. D. Rolleston in 1904, has not received the attention it deserves. Increased dosage of diphtheria antitoxin raises the incidence of serum manifestations, but diphtheria toxin exercises an inhibitory influence both in their frequency and intensity. In very severe cases the serum rash is late in development, scanty, or entirely absent. The presence of a rash even of a most limited nature is a favourable sign, while a well-marked urticarial eruption is an excellent prognostic. The occurrence of a secondary rash which is often accompanied by pyrexia and joint pains is a still more favourable sign, a severe type of paralysis being very unusual in such cases.—In a Clinical Study of Muscle Tone in Rickets, Dr. J. Douglas Galbraith maintains that the radiographic and clinical pictures in rickets whilst showing general agreement often present marked differences. The variation of calcium metabolism under different conditions, so far as ossification can be accepted as an index of calcium metabolism, suggests that the disturbance of this metabolism may be an accompaniment of rickets rather than the primary change. Dr. Galbraith emphasises the striking loss of muscle tone in rickets and brings forward clinical evidence to show that the disease may involve the muscles as well as the bones. He regards the condition of the muscles as a truer index of improvement than the radiographic picture. Once the muscle tone has increased the child improves both in ability to walk and in general health, no matter what the radiographic appearances may be. Bad hygienic conditions, especially confinement in a moist atmosphere loaded with the products of respiration, and an absence of moving air and sunlight, depress muscle activity and thereby are strongly predisposing factors in the development of rickets.—Mr. A. Ralph Thompson describes a case of Epispadias Associated with Complete Incontinence Treated by Rectus Transplantation, in a girl aged 5 years, the principle of the operation being as follows: The right rectus muscle is divided just below or at the level of the umbilicus, split and turned downwards, the split ends being placed in a dry wound which is made around the orifice of the "urethra" in the male and around the whole vulvar orifice in the female. The distal ends of the split muscle are united to each other, so that a sort of sphincter urethræ is formed. Mr. Thompson objects to the method of transplantation of both recti on the following grounds: (1) It will prolong the operation; (2) if for any reason it should fail, transplantation of the ureters alone remains, whereas if the transplantation of a single rectus should fail, the other one may be brought down before ureteric transplantation is employed.—Dr. Angelica Panayotatou, of Alexandria, gives an account of Twenty-five Cases of Whooping-cough Treated by Injections of Ether. All the cases were cured in 12–15 days from the beginning of treatment by intramuscular injections of ether in doses of 2 c.cm. every second day. The rapid recovery was all the more remarkable as the patients were poor working-class children of feeble constitution and poor organic resistance.—The abstracts from current literature are devoted to tuberculosis.

New Inventions.

A CLOSED DROP ETHER INHALER.

THE drawback to the closed ether inhalers on the market is that it is very difficult or impossible to avoid giving too much ether, especially if one attempts to maintain anæsthesia with them. I have designed an apparatus, shown in the illustration, which is a modification of the one described by Dr. Paluel J. Flagg. It possesses the following advantages: 1. The apparatus is light and can be used with the patient's head in any position. 2. The ether container holds just over three ounces, which is sufficient for an hour or an hour and a half's anæsthesia including induction, depending on the type of patient. 3. The level of ether in the container, which is made of metal, can easily be read from a protected glass gauge. 4. The ether drops on to a spiral roll of silver-plated fine copper gauze; as it drops it can be seen falling behind a glass window. The rate at which the ether drops is controlled by a thumb-screw on the top of the container. 5. The spiral roll of silver-plated copper gauze is rolled in the long axis of the tube connecting the mouth-piece to the bag and in no way impedes the free passage of the patient's respirations. 6. The tube connecting the mask to the bag is of wide bore, thus permitting perfectly free breathing. 7. Just in front of the gauze roll is the entrance pipe for gas or oxygen as desired, so that the patient gets the gas without it having to pass over the gauze. 8. Also in front of the gauze is the entrance to the pipe leading into the bag through which ethyl chloride may be injected. 9. Between the gauze and the bag is a valve opening into the air, which valve may be opened to a greater or less extent as desired, so preventing the CO_2 concentration in the bag rising too high. This valve being on the under side allows

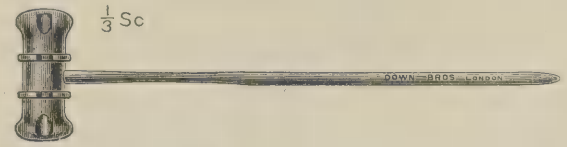


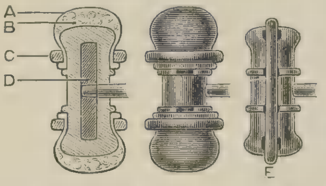
moisture and excess of ether, should it occur, to escape. 10. The bag is very easily removed for rinsing purposes, has a wide neck, and is of one gallon size. I would strongly recommend that anyone using the apparatus should be thoroughly familiar with the closed ether technique.

The apparatus is made by Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, London, W. 1.

F. P. de Caux, L.R.C.P. Lond., M.R.C.S.

THE "UNIVERSAL" PERCUSSION HAMMER.





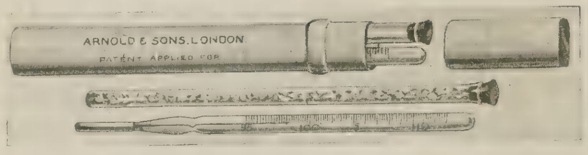
A, Rubber cap. B, Cotton-wool. C, Rubber ring. D, Metal core. E, Larger rubber ring.

The illustration shows a percussion hammer which is capable of several adjustments, thus enabling it to be employed for a number of different purposes in the clinical examination of the lungs, heart, and nervous system. It is claimed that it can be used in ordinary percussion instead of the finger or rigid plessor. By means of rubber caps and rings, the striking surface can be changed from a hard to a softer, slightly yielding form, more closely simulating the finger. The handle is flexible and thus enables the force of the percussion to be varied easily and the blow made to be short and rapid rather than sustained. It can also be used in the testing of reflexes, and here again the adjustable character of the part used for striking is an advantage—e.g., when one extremity is padded, it may be conveniently used to elicit the jaw reflex, the wrist- and elbow-jerks. The free extremity of the handle is pointed and rounded, thus permitting it to be used in testing the plantar and the superficial reflexes. A further use to which this instrument may be applied is in testing for thermo-anæsthesia, since pledgets of cotton-wool, wetted with hot and cold water respectively, may be placed under the rubber caps at the ends of the hammer and thus applied to the skin.

We have tested this instrument and found that it is useful for the purposes mentioned and that it justifies the claims put forward for it. It is supplied in a small neat case by Messrs. Down Bros., Ltd., 21 and 23, St. Thomas's-street, London, S.E. 1.

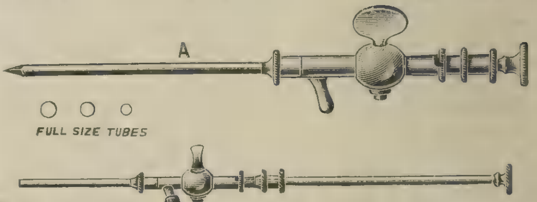
ASEPTIC CLINICAL THERMOMETER CASE.

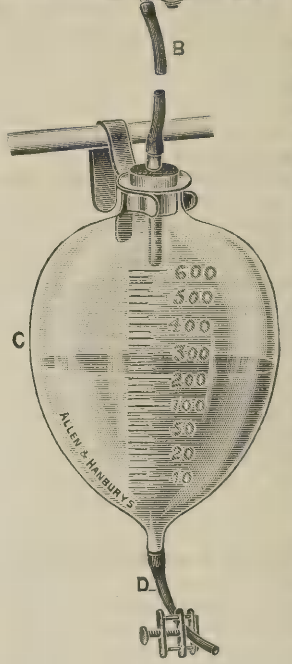
The illustration shows an improved thermometer case which I have had in use for nearly 12 months, and which I find acts perfectly. Clinical thermometer cases are known which are adapted to contain disinfectants; my object is to avoid the repeated use of the same disinfectant while at the same time facilitating the carriage of a disinfectant with the thermometer case, so that it is always ready to hand. The thermometer case shown has two compartments, one for the thermometer, the other being fitted with a glass tube in which permanganate of potash crystals or any other suitable solid disinfectant may be carried; this tube has a small hole at the lower end. When required the tube is removed and a few crystals of disinfectant are shaken into a glass of water to form a solution in which the thermometer is immersed. This allows the thermometer to be disinfected by the bedside of the patient.



The makers are Messrs. Arnold and Sons, 50–52, Wigmore-street, W. 1. Charles Pentland, M.D.

AN IMPROVED ASPIRATOR.





The aspirator here illustrated consists of a Potain trocar and cannula, A (made in three sizes), and a bottle, C. The top opening in the bottle is fitted with a rubber cork perforated by a glass tube, which is connected with the needle by a rubber tube, B. The bottom opening is fitted with a rubber tube, D, which can be clamped. To use the apparatus, the tube D is clamped and the bottle partially filled with water. The cork is put on and the bottle hung at the side of the bed. The needle is then put into the pleural cavity, the trocar withdrawn beyond the stopcock, which is then turned off. The tube D is then unclamped and the water running out of the bottle produces a suction which draws the liquid from the pleural cavity. The trocar can be detached from the needle beyond the stopcock and if this is done a specimen of the effusion can be obtained for analysis. The chief advantages claimed for the apparatus are: 1. It is simple and inexpensive. 2. The physician does not have to occupy himself with pumps, &c. When once started it works itself, and it is quite easy to do a gas replacement single-handed. 3. The flow of the liquid is even. During a gas replacement it is possible to keep the intrapleural pressure absolutely constant throughout.

The apparatus can be obtained from Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, W. 1.

L. S. T. Burrell, M.D., M.R.C.P.

A NEW INHALER FOR OBSTETRIC WORK.

Dr. P. A. Mansfield, of Sevenoaks, calls our attention to an apparatus which he has been using for the last three years and for which he claims that the maximum effect is obtained from the minimum dose of chloroform. It consists of a face-piece with an expiratory valve and an air port for safety during deep breathing. The construction of the chloroform bottle is such that the inspiratory effort of the patient sucks air through the chloroform. The two pieces of the apparatus are joined together by flexible rubber tubing.

THE LANCET.

LONDON: SATURDAY, OCTOBER 6, 1923.

OURSELVES.

With this issue we enter our 101st year, and the occasion has been taken to give a sketch of the history of The Lancet, from which, it is hoped, an estimate may be made of the aims which have been before the paper since its foundation, and the degree of accomplishment attained to. We record now our deep gratitude to those who have permitted us to publish their congratulatory messages; it is our earnest hope that future work will in some proportion justify our pride in such testimony.

◆

BIOCHEMISTRY AND MEDICINE.

Perhaps no subject has advanced so rapidly during the last 10 years as biochemistry. It was formerly regarded by the clinician as an academic subject, interesting to the physiologist and pathologist, but quite outside the range of practical medicine. Scarcely any English hospital possessed a separate department for the chemical investigation of its patients, while the chemical investigations made were performed in side rooms attached to the wards or else in some small room or unused corner of the pathological department. The examinations were restricted almost entirely to urine, and were done by the physicians themselves, their clinical clerks, or some junior member of the pathological staff who was looking forward to the time when he could give up an irksome duty. To-day the conditions have completely changed: every hospital of any size at all has a chemical pathologist, with a separate department to himself. In Canada and the United States the biochemical department of the hospital is quite as large and important as the pathological institute, and it plays just as important a part in the diagnostic and therapeutic side of medicine as the X ray department.

What has caused the sudden growth of biochemistry and its adoption by medicine? The pioneer work was undoubtedly done by such workers as Emil Fischer, Hammersten, and Abderhalden, but in Germany the subject was pursued more on purely chemical lines. The workers themselves were primarily organic chemists, and not medical men. America was the first to employ chemical methods as a routine in the investigation of patients, and for this work men were employed who were primarily medical, but with special chemical training. Perhaps this forms a clue to the question as to what was the stimulus resulting in the rapid growth of biochemistry in medicine. F. M. Allen's monumental work on diabetes mellitus may have been that stimulus. His investigations showed clearly the value of working out each patient's metabolism, and clinicians all over the world were quick to adopt his methods. Quantitative estimation of the urinary sugar was combined with a careful consideration of the chemical constituents and the calorie value of the patient's diet. This technique seems to have been the first to demonstrate the practical value of careful biochemical investigation in the patient's treatment. At the time of its introduction blood-sugar estimations were very difficult, and in most cases quite outside the range of practicability. Large quantities of blood were required for a single determination, and the technique was elaborate and intricate. The want of accurate and moderately simple methods of sugar analysis brought home the need for reliable systems of blood analysis: the response was soon forthcoming in the form of Prof. Otto Folin's excellent methods. Using his system it is possible to determine urea, non-protein nitrogen, uric acid, amino-acid nitrogen, sugar, creatinin, and chlorides on 10 c.cm. of blood in a very short time. The technique is so simple that an unqualified laboratory assistant in constant practice can be trained to carry out the routine analyses. Many other systems of analysis could be quoted, such as Benedict's or Meyer's, all possessing special virtues of their own.

If it is granted that diabetes mellitus formed the original stimulus for the development of medical biochemistry, it is certain that the same disease has been responsible for reinforcing its position in modern medicine. The advent of insulin therapy has clearly demonstrated the value of this subject, and it might not be going too far to state that insulin could never have been discovered without the aid of some accurate methods of micro-chemical blood analysis. After all, the value of insulin is manifest by its immediate action on the blood-sugar, the urinary changes being apparent only after some time. Without blood-sugar determinations standardisation of the preparation would be impossible. Over 10 years ago Rennie experimented with extracts made from the principal islet of certain teleostean fishes, and was able to demonstrate certain effects on the metabolism of the diabetic patient. One wonders what success he would have had if there had been some simple clinical method of estimating blood-sugar at the time. This worker's position can be realised by imagining insulin therapy without blood-sugar determinations. With urinary sugar alone available as a means of judging the result of treatment many disasters would occur. The treatment of diabetes has always been a problem to medical men, and admittedly insulin has, to a certain extent, made it a more difficult one. In the compendium of experiences on insulin medication summarised in The Lancet last week is an account of observations on 161 patients by Allen and Sherrill, who conclude, with obvious justification, that "insulin has tremendously improved diabetic treatment, but has not simplified it." The elaborate controls required in the treatment of the refractory case described by workers in the Medical Investigation Department of Guy's Hospital (see p. 777) are another example of the intricacies of the relations between diet, blood-sugar, urinary sugar, and insulin dosage. Matters proceed quite smoothly whilst the patient is in hospital, for here he can command the attention of people qualified to administer his doses of insulin and to perform the necessary analyses, but when he leaves matters are very different. His medical adviser can administer the daily dose of insulin, but what about the blood-sugar determinations? With a case that has been worked out in hospital, the practitioner's task is fairly simple, since he need only administer the dose advised as a result of this investigation, and provided that there is always a trace of sugar in the urine all will be well. The real problem is presented by the case coming to the practitioner for the first time with bad glycosuria, and refuses for one reason or another to go into hospital. Again, a case verging on coma may be encountered.

It is impossible to commence insulin therapy without a knowledge of the blood-sugar content at the outset. It has been stated that the practitioner can himself estimate the sugar in the blood, and sets of apparatus are on the market for the purpose at quite low figures. During the last six months a large number of medical practitioners have visited chemical pathologists asking for advice and tuition on the method most suited to their needs. Speaking generally, two methods are open to them: the volumetric method of MACLEAN or the colorimetric method of FOLIN. The former is cheap in the way of necessary apparatus, but requires a great deal of skill, whilst the latter is easy but expensive. A good colorimeter is an absolute essential to FOLIN's method, and this may cost anything in the region of £30. Choice falls usually on the first method, but too often, after a short period in the laboratory learning the technique, the attempt is abandoned. For the most part the busy doctor cannot give the necessary time, and therefore cannot obtain reasonable results. It is impossible to become a chemical pathologist after a few days' training. For the solution of a difficult position there are two possibilities. The first is the one adopted by the United States and Canada. There every patient undergoes a preliminary course of treatment in hospital where his dose of insulin and diet are worked out. During this time the patient is taught about his disease, how to test his own urine, and how to sterilise a syringe and to administer his insulin. When the investigations are complete, which is usually in about a fortnight, he is sent out with a supply of insulin and urine-testing outfit, and is told to report to his doctor once a month. If any sugar appears in the urine he returns to hospital at once, where a new diet is worked out for him. According to workers in those countries the scheme works admirably. The other solution is for the blood analysis to be done at some central institution, just in the same manner that Wassermann reactions are done for many doctors. Prof. FOLIN suggests that blood may be suitably preserved for sugar determinations by the addition of a little formalin. This has been tried and has been found to work splendidly. Bloods have been kept as long as 56 hours without any change in the blood-sugar being demonstrated.

STATE CONTROL OF HOSPITALS.

ON another page our Australian correspondent summarises an important new measure for the control and coördination of hospitals in the State of Victoria. All charitable institutions, he explains, will now have to be registered; no financial appeal may now be made, and no contributions may now be received, on behalf of any unregistered foundation; in addition the State has armed itself with power to close or amalgamate hospitals and to declare the use to which they may be put. Many social developments initiated by the Governments of Overseas Dominions have ultimately been adopted by the mother country, but, with our admirable voluntary hospital system and our absence of enthusiasm for central control, it is unlikely that in this lead England will quickly follow the lead of Victoria. We in this country have never had any adequate system of registration although a hundred years ago Parliament did direct that charitable donations should be registered in order to avoid loss and encourage payment. Nor have we any control over charitable appeals, except that the police regulate street collections and except that (quite unofficially) a few journals and some societies display a certain vigilance in these matters. As for any coördination of hospitals in England or any power to close them or rearrange their objects, we can produce no example except the control exercised within strict limits by the Metropolitan Asylums Board over the various institutions which it administers. Our Ministry of Health, on its inception in 1919, was ordered by Parliament to take steps to coördinate measures conducive to the health of the people, but in the matter of hospitals the Ministry has not a clean slate upon which to write. For the history of our hospital legislation is ancient and intricate. It is interwoven in its early stages with religious foundations, maisons de dieu, and houses of correction for the poor. There are inconvenient chapters about mortmain and the doctrine of charitable uses. But if the law has sometimes disallowed bequests for philanthropic objects, it has given cast-iron support to anything in the nature of a trust. The Charity Commissioners may here and there permit the sale of a site or may encourage the making of some minor change by means of a private Act of Parliament, but, on the whole, would-be reformers and coördinators have no primrose path to tread. Countries with less history have more opportunity. Already in different parts of Canada and Australia legislatures are finding it necessary on the one hand to organise new municipal hospital districts based on public finances and, on the other hand, to regulate the conduct of private hospitals. The measures now initiated in Victoria may be adopted elsewhere within the Empire. If we cannot imitate them in this country, and if, indeed, we may not wish to do so, we shall nevertheless watch their progress with keen interest.

◆

THE FUTURE OF NEUROLOGY.

NEUROLOGY to-day stands in a peculiarly interesting position. No thoughtful observer can fail to be impressed with the existence of conflicting tendencies which do not make for progress; the neurologist himself is well aware of a change in outlook and scope which will have to be faced squarely if he values peace of mind. We do not know when the term "neurologist" came into vogue, nor, for that matter, can we define the limits of his specialty, but we have always supposed it concerns the totality of the problems presented by the nervous system in health and disease. The later decades of last century and the earlier years of this constituted a period of immense activity in neurological classification and description, a time when the clinico-pathological method ruled supreme, when the neurologist busied himself with numerous problems of organic nervous disease and utilised anatomical and physiological data as a basis on which to erect his knowledge of his subject. Trained in this eminently reasonable fashion, grounded on the firm foundation of anatomy, he proceeded to deal with nervous disease as it presented itself to him clinically without any uneasiness in respect of his competence to deal with every type of case. While one might be more interested in "organic" and another in "functional" clinical material, neither felt any embarrassment in handling a case of hemiplegia or of hysteria indifferently. Some of the greatest neurologists of other years—CHARCOT, WEIR MITCHELL, HUGHLINGS JACKSON—made contributions to both organic and functional neurology of surpassing interest and worth. No distinction prevailed between the "organic" and the "functional" for the simple and adequate reason that no distinction was considered to exist. In his consulting room the neurologist felt his activities did not automatically cease at the level of cerebral tumours ; he considered himself justified in administering to the mind diseased because he regarded the brain as the organ of mind, and he was familiar with the anatomy and physiology of the brain.

A change has come over neurology since the war ; a war legacy which the pre-war neurologist may be pardoned for not, perhaps, welcoming altogether without reserve. Even before that period what had been tacitly considered the neurologist's field had been steadily encroached on by bacteriologist, syphilologist, endocrinologist, and internist ; a movement, needless to say, the outcome of which has been beneficial to all concerned, for the investigations of these other specialists were conducted on clinico-pathological lines and have resulted in permanent additions to our knowledge of the nervous system. Psychiatry, too, stood to benefit by the application of similar bacteriological and other lines of research to its manifold problems. No one interested in the study of nervous and mental disease ever doubted the value of a combined approach of this description to the outstanding difficulties of his subject, just as to-day he is confident of the usefulness, nay, the indispensability, of the contribution which the biochemist can offer. The change, however, to which allusion has been made is of another kind. The study of functional nervous disease and the treatment of functional nervous cases seems to be passing to some extent into the hands of a generation of self-styled "neurologists," not a few of whom—it may be said without exaggeration and without offence—seem to act as though knowledge of the anatomy and physiology of the nervous system were immaterial, if not an actual hindrance. Satisfied, it may be, by the assurance of other investigators that no "organic signs" are present, they proceed to treat their cases by methods called "psychological," methods in which all consideration of the somatic condition of the patient is eschewed. The "clinical psychologist" of to-day finds support for his persistent attempt at an artificial separation of one variety of neurological case from another in the most recent work of Prof. William McDougall,[1] who declares that any psychology based on the assumption that man is merely a mechanical structure is unprofitable and misleading. Prof. McDougall holds that biophysical, biochemical, and physiological knowledge does not take us any distance in the direction of solving problems of regulation and adaptation, that the doctrine of localisation of function in the cerebral cortex is "rocking insecurely," and that "the only wise course for the psychologist . . . is the bold one of asserting the relative independence of his science." Almost 20 years ago the same writer published a valuable little primer [2] in which he endeavoured to show "how each of these two bodies of doctrine, the physiological and the psychological, supplements the other, deepening our insight into the processes that result in the actions of men and animals, and how the conjunction of the two kinds of research brings before us a number of problems of the deepest interest that remain hidden so long as we confine our attention to one or other of these sciences." Curious, indeed, is the impression left on the mind by the conjunction of these two citations. The student of the subject may be allowed to decide which Prof. McDougall he prefers.

For ourselves, we believe that efforts to divorce disease of the mind from disease of the nervous system are doomed to failure. From the standpoint of the clinical neurologist, we see nothing but confusion and therapeutic nihilism confronting all such attempts. Not only is it impracticable to decide where functional symptoms end and organic symptoms begin, and arbitrary to assign each category to the ministration of distinct types of specialist ; it is equally unsatisfactory to suppose that since neurophysiological knowledge is, in the opinion of Prof. McDougall, "astonishingly defective," it can throw no light on the problems of the clinician. The latter welcomes any light on his subject, from any source ; he is no more intolerant of the approach made from above by the psychologist than he is of that made from below by the physiologist ; but he objects to any doctrine which would compel him to believe that function and structure are not interrelated, that the phenomena of mental disease are not to be studied in connexion with a disordered nervous system, that the world of the psyche is a realm apart, unapproachable except by psychological methods. In his thoughtful presidential address before the American Neurological Association in 1921,[3] Dr. Sidney Schwab, of St. Louis, points out clearly the applicability of neurological ways of study to the problems of mental disorder. As a teacher, he has noted the ease with which the student examines a case of tabes and his awkwardness and embarrassment in the presence of a case of dementia præcox. That a different kind of thinking is required in one case as compared with the other is surely an unwarranted assumption. Psychological methods of investigation are as material as any employed by the neurologist. Did the student realise that, as Prof. R. J. A. Berry [4] puts it, the same type of neural machinery which serves for the simpler reflexes is also utilised, though in an immensely more involved form, for the display of emotions and of mind, he would be less conscious of hesitation, and his dilemma would disappear. Prof. Berry urges the medical man to remember the formula—no neurone, no mind. Weighty are the accumulations of objective evidence exemplifying the interrelation of the two aspects of neurological research. The neurologist brought up in the school of organic study must assimilate the knowledge of the working of the mind gained by those who have approached the subject from another angle, just as these, in their turn, ought not to remain indifferent to progress made along anatomo-physiological and other lines. Psychology, we are convinced, will suffer if it separates itself from the problems of medicine as a whole.

Measurement of Progress in Public Health.—The William Farr Lecture, by Sir Arthur Newsholme, will be delivered at the London School of Economics and Political Science, Houghton-street, Aldwych, W.C., on Oct. 4th, at 5 P.M. The chair will be taken by the Minister of Health.

Condensed Milk Regulations. — Regulations were made by the Minister of Health on May 1st last providing for the manner in which any tin or other receptacle containing condensed milk is to be labelled or marked, and prescribing the minimum percentages of milk fat and milk solids in condensed milks. The date fixed for the operation of the Regulations was Oct. 1st, but as difficulties have arisen in consequence of the recent dock strike in disposing of stocks of condensed milk already in this country which do not comply with the Regulations, the Minister of Health has decided to postpone until Nov. 1st the operation of the Regulations in regard to retail sales in this country. Amending Regulations to give effect to this decision will be issued within the next few days. It is not intended to alter the date fixed for the application of the Regulations to condensed milk imported into this country—viz., Oct. 1st.

Annotations.

"Ne quid nimis."

THE PASSING OF THE PILL-ROLLING CHEMIST.

TIME was when every pill and potion was concocted on the spot by a chemist skilled in the handicraft as well as the theories of his calling. During the last decades a great and rapid change has taken place in the duties of the dispensing chemist, who is becoming more and more a salesman of ready-made drugs, and less and less of a dispenser weighing out and compounding remedies from a doctor's prescription. No doubt a good deal depends upon the class of practice, and there are still many dispensers who are kept quite busy at their proper work. Opinion may vary whether the change described is or is not for the better, but it is certainly proceeding steadily and irrevocably, and it is well to take stock of it, to see whither it is leading us, and in what ways, if any, it may be modified or diverted for the public good. This subject has lately been under discussion in the Danish medical press, and it is possible by a study of conditions in Denmark to obtain a bird's-eye view of some aspects of the problem as it presents itself in England.

The Danish regulations controlling the dispensing of drugs in chemists' shops are numerous and far-reaching. The chemist is liable to unexpected visits of inspection, and the cleanliness of his hands, the weight of his aspirin powders, and the confinement of poisons to the poison cupboard are all matters over which he may come to grief. It is one of the anomalies of the present changing state of affairs that while the small dispensing chemist is thus carefully policed, the wholesale manufacturing chemist, whether he be a native of Denmark or a foreigner, is under only lax control. His compounds may, and probably do, contain the exact quantities of the drugs indicated on his labels. It is, of course, in his own interests that his wholesale dispensing should be conducted on the most accurate and reliable lines, and it is probable that the chances of errors of dosage are smaller in his hands than in those of the retail dispensing chemist. But it is safe to venture the forecast that the time is not far distant when the wholesale manufacturing chemist will be under as close official supervision as his small competitors. From the point of view of the public's purse the change to which we have referred may be for the better. The hand-rolled pill made to order must inevitably cost more than any manufactures turned out in thousands. Recent advances in physical chemistry have greatly strengthened the hands of the manufacturing chemist, and now that such considerations as osmotic pressure, sterility and hydrogen-ion concentration of drugs for parenteral injection have come to the fore, it is inevitable that the old-time dispensing chemist should be unable to fulfil all that may be required of him. He is not, and it would be unfair to expect him to be, a bacteriologist. But, being neither a bacteriologist nor a machine capable of mass production, it is inevitable that he must sooner or later become a connecting link between the manufacturing chemist and the public.

As regards the manufacturing chemists it is evidently desirable that his products shall be under as close control and supervision as those of the small dispensing chemist whom he is displacing. Even the manufacturing chemist may, like Homer, be caught nodding, and a case has recently been reported in which a firm of manufacturing chemists with a world-wide reputation sold a preparation supposed to contain a ferment of such-and-such potency and capable of withstanding the action of the hydrochloric acid of the gastric juice. Tests showed this preparation to contain the ferment indicated on the label, but this ferment was destroyed in a few minutes by n/100 HCl. No doubt such cases are rare and probably a vanishing quantity in regard to firms of high and established reputation, which have nothing to fear and, indeed, everything to gain from the inspection which is required to keep up the standard of the laggard. The old order of dispensing is giving place to new, but let us make sure that the new order is of the best.

THE BENZOATE TEST FOR RENAL FUNCTION.

THE interest in tests devised for showing renal inefficiency has grown considerably of late years. Undoubtedly the opportunities provided by the war acted as an important stimulus for research into kidney function tests; the work of Prof. H. Maclean can be quoted as perhaps the best example of the use made of systematic examination of soldiers. Tests of renal function can be divided into three headings: Firstly those in which the partition of various substances between blood and urine is examined; secondly, those depending on the administration of some foreign substance, such as a dye, and observing how rapidly and completely the kidney excretes it; and finally, the renal function can be tested by determining the excretion of some substance native to the individual. The blood-urea test is an example of the first group, the phenolsulphonephthalein test is typical of the second group, whilst Prof. Maclean's urea-concentration test is perhaps the best known instance of the third group. The benzoate test of Swanson and Kingsbury also belongs to the last-named category. In their original paper, published in the form of a report to the Society of Biological Chemists in December of 1920, these authors called attention to the fact that hippuric acid is the only urinary constituent synthesised by the kidney. As is well known, the kidney conjugates benzoic acid with glycine and the resulting hippuric acid is excreted into the urine. That the greater part of the hippuric acid occurring normally in the urine depends on the amount of benzoic acid ingested in the food had been proved previously by other workers and was confirmed by the authors. These physiological facts suggested a new test for renal functions, and in a more recent paper[1] Dr. F. B. Kingsbury describes some of the results obtained with it. The test proper is performed on the patient as soon as he rises from his bed in the morning. The only preparation necessary is that he must be forbidden to eat fruit of any kind, since the amount of benzoic acid contained is quite enough to upset the interpretation of the test. On rising the patient empties his bladder, and immediately drinks a solution of 2·4 g. of sodium benzoate in about 100 c.cm. of water. The container is rinsed out with about 200 c.cm. of water and this is also drunk. After an hour has passed another 200 c.cm. of water is taken, making a total of 500 c.cm. of fluid in all. The bladder is emptied at the end of the second hour and also at the end of the third hour, both specimens being preserved for subsequent analysis by the addition of 10 drops of a 10 per cent. solution of thymol in chloroform, and 15 c.cm. of 2 per cent. nitric acid. The volume of each specimen is measured and an aliquot specimen is taken for analysis. The author, working with medical students, found that 82 per cent. of the ingested sodium benzoate was excreted in the two-hourly specimen and that 16 per cent. was the average for the third-hour specimen. A series of pathological cases are given by Dr. Kingsbury, and it is shown that in cases of impairment of renal function the excretion of hippuric acid under the above conditions is markedly decreased. It is also claimed that the test gives positive information in very early conditions, when other well-known tests, such as Maclean's urea-concentration test and Volhard's water-excretion test, indicate little or no impairment of the renal function. Positive results are said to be obtained in cases having normal blood analyses. It is to be noted, however, that all the cases described possessed well-marked clinical symptoms, and that none of them could be called very early cases of kidney damage. The benzoate test has apparently not yet been tried in this country; but if the claims of the authors are borne out it should become an important method of examining the kidney function.

THE BACTERIOPHAGE IN DRINKING WATER.

Certain obscure phenomena which are noted from time to time in the routine bacteriological examination of drinking waters may possibly be ultimately traced to the action of d'Herelle's bacteriophage. As an instance of this, which has now become almost classical, one may cite the experiments of Hankin, which were published in 1896, upon the bactericidal properties of certain Indian river waters. This observer noted that the water of the Jumna, just below Agra, contained over 100,000 organisms per c.cm., but that 5 km. further down the river only 90–100 organisms were present. On further investigation it was found that in test-tube experiments the filtered water exerted a marked lethal action upon the cholera vibrio, whilst after boiling no such action was present. Hankin attributed this effect to a volatile substance which he failed to isolate. D'Herelle, who has redirected attention to these experiments, considers it an undoubted example of bacteriophagic activity. The possibilities latent in these lytic substances have been recently examined, from another point of view, by Sir Alexander Houston and his colleagues.[1] One of the bugbears of the water bacteriologist is the impossibility of deciding whether typical colon bacilli, whose presence in waters is a matter of so much importance, are of human or animal origin. Since if derived from the latter they would be regarded with much more lenience than in the former case, it would be a matter of great practical utility to have a simple test which would afford such a distinction. At the Metropolitan Water Board's laboratories a comprehensive series of experiments has been undertaken to find out if such a differentiation could be obtained through the medium of the bacteriophage; it being thought that strains of human origin, and lytic for the human colon bacillus, might be discovered which would constantly lyse these organisms and be without action upon types of colon bacillus derived from animal sources. These experiments, though extremely interesting in their details and worthy of perusal on account of the information they contain as to bacteriophages in sewage, and upon certain technical points, have proved abortive, as was rather to be expected from a knowledge of the wide activities of the bacteriophage already exposed by d'Herelle. In connexion with the whole question of the activities of these widely disseminated substances in drinking waters, we also call to mind the well-known decrease in bacterial content which takes place in many waters when stored, and the oligodynamic action of certain waters. These phenomena have been attributed to electrolytic action, producing agglutination of the organisms and an apparent instead of a real diminution, and to the lethal effect of minute quantities of salts of the heavy metals. It may well be that this disappearance of bacteria is sometimes due to bacteriophagic action. Experiments of Miss Lepper[2] have shown that when added to emulsions of bacteria the initial killing by the bacteriophage is very rapid; but that after a period the rate of the process slows off, and becomes progressively slower as the limits of the experiments are reached. It would appear, therefore, that where the bacteriophage is much diluted and the organisms, relative to experimental conditions, are extremely few—a state of affairs which would obtain in stored drinking water—the great dispersion of the two active factors, bacteria and bacteriophage, could well produce the relatively slow disappearance of bacteria which is sometimes so striking an occurrence.

THE PROBLEM OF THE DIPHTHERIA CARRIER.

A rather pessimistic paper on the control of diphtheria carriers has lately been published by Dr. Max Christiansen[1] of the Blegdam Fever Hospital in Denmark. It would seem that two or three negative bacteriological reports are of little value when diphtheria patients are ready to be discharged from hospital. Among 100 such cases there were as many as 40 in which three negative examinations for diphtheria bacilli were made and in which, at a later date, these bacilli were found. Experiences such as this afford an explanation for the old observation that "return" cases are as frequent when a diphtheria patient has been discharged from hospital with a negative report, as when he has been discharged with a positive report. At the Blegdam Hospital the rule has been adopted of not transferring diphtheria patients to other hospitals until five examinations of both nose and throat have proved negative. Even so, the mesh of this net seems to be too coarse to retain every infectious case, and were it to be made fine enough for this purpose, the cost of running a fever hospital would be exorbitant. Another disconcerting observation made by Dr. Christiansen is that the aural discharge in cases of scarlatina frequently contains the diphtheria bacillus. He has observed as many as 28 such cases, in 11 of which diphtheria bacilli were also demonstrable in the nose or throat. How, in the remaining 17 cases, diphtheria bacilli came to be limited to the discharge from an ear, he is at a loss to explain; it was highly improbable that these patients were infected during their residence in hospital, for bacteriological examinations were made at the time of admission to hospital as well as later. Dr. Christiansen adumbrates the possibility of the scarlatinal infection of the throat and nose having displaced the diphtheria bacilli from these two sites, whereas it was incapable of doing so from the external ear. His demonstration of diphtheria bacilli not only among many ex-patients, but also among many school-children who had apparently never suffered from diphtheria, have led him to adopt a sceptical attitude as to the efficacy of strict and wholesale isolation except under primitive and transparent social conditions. The problem, in his opinion, is more likely to be solved by employing the Schick test for discovering susceptible persons, and by vaccinating such persons according to Behring's technique.

THE SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS.

It is a significant sign of the times that the whole of the October number of *Tubercle* is devoted to the surgery of the lungs and the pleural cavities. The treatment of surgical tuberculosis, it would seem, is steadily becoming more conservative, while the treatment of pulmonary tuberculosis—that hitherto jealously guarded preserve of the physician—is becoming every year more surgical. A special bibliography, published in this number of *Tubercle*, of articles on chest surgery, is remarkable for this that though it covers as short a period as 1920–23, it yet runs to almost five pages. In the first original article Mr. H. Morriston Davies traces the progress made in this direction during the last few years. He finds that the operations of extra-pleural pneumolysis and thoracoplasty are indicated only when treatment by artificial pneumothorax has been given a fair trial and has proved impracticable. As for the results of the thoracoplastic operations, estimates vary considerably according to the choice of case, the skill of the operator, the financial status of the patient, the quality of the after-treatment, and various other factors. Mr. Morriston Davies has achieved freedom from symptoms or much improvement in 50 per cent. of his cases, and his operation mortality is only 8·3 per cent. This mortality could probably be appreciably reduced by improvements in the anæsthesia adopted. This is such an important aspect of the problem that it is dealt with separately in an original article by Dr. L. W. Shelley, who discusses the choice and the method of administration of the anæsthetics most suitable for these radical operations. In a review of another paper which also deals with the problem of anæsthesia, Prof. Bull of Christiania asks: Why did eight patients die within a few days of the operation? He notes as significant the fact that the clinical picture was remarkably uniform. These post-operative fatalities did not usually overtake patients leaving the operating theatre in an exhausted state, and with a pulse of 120 or more. In fact, the patients who died a few days after the operation often seemed to stand it wonderfully well. When the solution is found to this riddle, it may confidently be expected that this operation will enjoy much greater popularity than it does at present. Another drawback to this operation is the fear of an open pneumothorax, and the slow development of chest surgery, as compared with abdominal and even head surgery, appears to have been mainly due to an almost morbid fear on this score. Now that the mechanism of mediastinal flutter and other sequels of an open pneumothorax is more fully appreciated, the bugbear of yesterday has to-day become a fairly well-controlled incident. The surgical treatment of pulmonary tuberculosis has been slow in achieving recognition in this country, but we may find a certain consolation in this that we are now beginning to benefit from the experiments and mistakes of pioneers in other countries.

DELAY IN PUBLICATION OF ACTS.

ON the last day of July the Rent Restriction Act of 1920 expired. On that same day a new Act received the Royal Assent and came forthwith into operation. Apart from introducing still further complications into the relationship of landlord and tenant—a matter which affects most of His Majesty's subjects—it contains provisions as to certification of dwelling-houses by sanitary authorities which are of special importance to public health administrators. But, though this Act came into force on July 31st, it was nearly a fortnight before an official copy of it was available for the public. Complaints of the delay appeared in the daily press, and even county court judges had to adjourn cases for want of information as to the law they were to administer. The same dilatoriness was displayed in other instances which more particularly concerned the medical profession. The brief Dentists Act took a full fortnight to produce. The Salmon and Freshwater Fisheries Act, which contains sections on Rivers Pollution, was a longer document and not available till nearly a month after it was passed. As is usually the case, it had been in print in Bill form for many weeks previously, and the wording required but the most trivial alterations when the Bill became an Act. It is true that the Fisheries Act does not operate until the end of the year, but postponed operation is no justification for postponed publication. Indeed, if these delays continue, it would be only fair if Parliament made it a rule never to pass an Act which took effect from the date of passing. The situation is even worse if we turn to the local Acts, many of which are of considerable importance to public health authorities and medical officers. It may seem incredible, but it is the fact that some of the local Acts passed in the middle of July, and many of those passed at the end of July, are even now not yet available to those whom they concern. The position in fact recalls the anecdote of the draftsman who many years ago was urging Whitehall to revise and consolidate the Food and Drugs Acts which were then, as they are now, a not entirely perfect body of law. A prominent official is said to have protested that there was no necessity for such a measure. "We understand the Acts inside the department, and the public finds out in the police court." If this cynical attitude does not survive in Whitehall, it might be suggested to the King's Printer that he should expedite his statutory publications. We believe it is a legal principle, perhaps we should call it a legal fiction, that we are all supposed to know the law. If so, there is no more urgent work before the official printers than the issue of Acts of Parliament.

There is another point not without effect upon the accessibility of legislation to the citizen who has to obey it. There has been a regrettable increase in the price of Acts. The Public General Acts passed last year cost a good deal more than a pound to purchase separately, and though, for those who could manage to wait till the end of the year, a collected edition ultimately appeared at the price of half a guinea, this latter price compares most unfavourably with the pre-war standard charge of 3*s*. which was invariably made for this volume, however great its bulk, down to the year 1918. As every Act had already been printed in Bill form, and as it must be printed for official use in any event, there seems no reason why the public should not be allowed to acquaint itself with the laws of the country at the cheapest possible cost.

THE ATTENUATION OF SMALL-POX VIRUS: AN EIGHTEENTH-CENTURY EXPERIMENT.

THE practice of inoculation against small-pox, as is well known, was first adopted in England in the early years of the eighteenth century, when it was introduced from Turkey through the letters of Lady Mary Montagu, wife of the British Ambassador at Constantinople. Towards the end of the century, when Jenner, in 1796, began to make experiments with cow-pox, inoculation as a preventive measure had spread widely over Britain, even to the remoter parts of Scotland. The operation was performed with the fresh crusts taken from a small-pox case, and although the disease so transmitted proved usually to be less severe than infection acquired by contagion, the idea of treating the crusts in any way so as to weaken their infective power while at the same time ensuring immunity had apparently not been entertained by any medical practitioner. But medicine has time and again registered a debt to those who, if not "quacks," at least were outside the pale of the profession, and it was a "Jack-of-all-trades" in the Shetland Isles who first put into practice the attenuation of the small-pox virus before transmission. His method was to "mature" the crusts from a small-pox patient for a number of years before inoculation. The story of his work is found in the "Statistical Account of Scotland," compiled by Sir John Sinclair, M.P. for Caithness, and published in 1791—in itself an interesting document and the forerunner of the general Census which was instituted in 1801. Sir John Sinclair memorialised all the parish ministers of Scotland for information on the natural history, population, and productions of their parishes, and in the report from Mid and South Yell, Shetland, the Rev. Mr. Andrew Dishington records the following:—

> "Population: The population of these parishes has of late years considerably increased. For this two reasons may be assigned: (1) The system adopted by the landholders of parcelling out their lands into very small farms, &c., ... and (2) the amazing success with which inoculation has been attended. Formerly the small-pox occasioned the most dreadful ravages in these islands; frequently carrying off a fifth part of the inhabitants. Now hardly any suffer by this disorder. Inoculation is successfully practised, even by the common people, but in particular by a person whose name is John Williamson, who, from his various attainments, is called *Johnny Notions* among his neighbours. Unassisted by education, and unfettered by the rules of art, he stands unrivalled in this business. Several thousands have been inoculated by him and he has not lost a single patient. His success being so remarkable, it may not be improper to take some notice of the method

he pursues, in case it can furnish any useful hints to persons of the medical profession. He is careful in providing the best matter and keeps it a long time before he puts it to use—sometimes seven or eight years. And, in order to lessen its virulence, he first dries it in peat smoke, and then puts it underground covered with camphor. Though many physicians recommend fresh matter this self-taught practitioner finds from experience that it always proves milder to the patient when it has lost a considerable degree of its strength. He uses no lancet in performing the operation but, by a small knife, made by his own hands, he gently raises a very little of the outer skin of the arm so that no blood follows; then puts in a very small quantity of the matter, which he immediately covers with the skin that had been thus raised. The only plaister he uses for healing the wound is a bit of cabbage leaf. It is particularly remarkable that there is not a single instance in his practice where the infection has not taken place and made its appearance at the usual time. He administers no medicine during the progress of the disease, nor does he use any previous preparations. He is a singular instance of an uncommon variety of talents, being a tailor, a joiner, a clock and watch maker, a blacksmith, and a physician."

Whether this method originated with him or not cannot be proved, but if it did, then this "orra man" anticipated much of the recent work which has been done on these lines.

"MEDICAL SCIENCE ABSTRACTS AND REVIEWS."

WITH its ninth volume, of which the first number appeared on Oct. 1st, *Medical Science Abstracts and Reviews* enters on a new phase in its career. Following changes made last year on the surgical side, now under the control of Mr. C. C. Choyce, new editorial arrangements in the Section of Medicine have taken effect. This great subject will be divided under the following headings, each controlled by the editor named: General Medicine, Prof. F. R. Fraser; Cardio-vascular Diseases, Sir Thomas Lewis; Metabolic Diseases, Prof. H. Maclean; Respiratory Diseases, Prof. J. C. Meakins; Diseases of the Nervous System, Dr. F. M. R. Walshe; while Prof. T. R. Elliott will act as associate editor for the whole section. Reviews and abstracts will continue to be published as before, but no attempt will be made to cover the whole output of medical publications; future reviews will deal on suitable occasion with selected articles or groups of observations. For abstracts the general policy will be that of selecting only such articles as appear to contain original information with conclusions based upon trustworthy methods of observation and thought. Of a select group of journals, however, all will be noticed completely as each issue appears, a full list of contents being given, together with abstracts of all the more important articles. In the October issue the current numbers of five journals—*Heart*, *Brain*, the *Journal of Experimental Medicine*, the *Journal of Infectious Diseases*, and the *British Journal of Experimental Pathology*—are thus treated, while reviews deal with Vincent's disease and with the work of R. Magnus and his collaborators on the pharmacology of the nervous system, with special reference to postural and other reflex reactions. Sixty-four pages are devoted to well-chosen abstracts, and an index of subjects and authors dealt with in Vol. VIII. concludes an admirable number, which contains also a key to the initials formerly given at the end of each review and abstract. This custom has now wisely been discontinued, the full name of each reviewer being set out. If complete anonymity is not to be preserved there is little point in publishing initials and withholding the key till the index appears.

We rejoice that the scope of the journal is to be less ambitious, in that any attempt to deal with the whole output of medical literature is to be abandoned. It must be admitted that in the past editing has not always implied selection and that certain sections have occasionally been overwhelmed by the contributions of one transcriber. The laudable anxiety to give due credit to foreign authors, whose work might not be easily accessible to British readers, has led to some strange results. For example, in a review of diseases of the spleen, purporting to be complete, a list of published cases of the rare Gaucher's disease omitted one published in the *Journal of Pathology and Bacteriology*, though its authenticity has never been in doubt. Again, when the mass of material dealt with is too great publication of abstracts of original articles must be long delayed and may ultimately give more pain than pleasure. If we stress some of the difficulties with which editors of this journal have been unable to cope in the past, it is only because the excellence of the matter in certain branches of medicine such as bacteriology, biochemistry, and radiology has set a high standard. The official organ of the Medical Research Council commands respect, and we believe that with this volume its usefulness, already unquestioned, will so increase as to make it a necessity for men practising medicine and surgery as well as those engaged in scientific research.

THE INSURANCE MEDICAL SERVICE.

As we go to press important decisions are being made on which depend the whole future of the panel service. Last week the Minister of Health met the National Health Insurance Consultative Councils for England and Scotland and on Oct. 2nd he received the Insurance Acts Committee of the B.M.A., when a final effort was made to make clear the standpoint of the doctors of the country. During the 48 hours following this meeting the considered reply of the Minister with the Government's offer was to be in the hands of the Insurance Acts Committee which had arranged to meet on Oct. 4th to consider the position. Between this date and Oct. 18th, when the annual conference of the Panel Committee takes place, meetings of practitioners will be held throughout the country in order that their representatives on the Panel Committee will be well informed as to the feeling of the profession on the term of service put before them.

COMPLEMENT DEVIATION IN TUBERCULOSIS.

A LARGE amount of investigation of the Bordet-Gengou reaction in pulmonary tuberculosis has been done in this country by Lisle Punch and Hope Gosse among others, and recently in Italy Dr. N. Parise has published the result of his own observations and researches which form an interesting comparison.[1] The antigen used by him consists of a bacillary emulsion prepared from old cultures of tubercle bacilli (three to four years) on agar, in which the agar is completely covered by a layer composed of numerous small scales, which are carefully scraped off and then subjected to a lengthy emulsification in a sterile glass mortar, 50 c.cm. physiological saline solution containing 1 per cent. carbolic acid being added drop by drop. This antigen keeps well at ordinary temperatures for 60 to 90 days. Experiments were made to show how the Bordet-Gengou reaction behaved (1) in healthy individuals, (2) in those affected with various non-tuberculous maladies, (3) in confirmed, and (4) in suspected tuberculosis. Out of 14 healthy individuals, in 13 the result was definitely negative; out of 51 cases of non-tuberculous diseases 48 were negative and seven positive, consisting of four of syphilis, and one each of malaria, echinococcus of lung, and influenza. Of 78 tuberculous cases, there were 24 in which Koch's bacillus was found in the sputum, 20 in which the clinical signs were definite with absence of tubercle bacilli in the sputum, and 34 in which the physical signs were suspicious. The results obtained were as follows: Of the first 24 cases the reaction was strongly positive in 22 and negative in the other two, who were in the last stage of the disease. The explanation of this is to be found in failure of production of antibodies, due to a condition of anergy which is commonly met in tuberculous patients in the terminal stages. It was for this reason, moreover, that the experiments were conducted with a serum obtained from patients certainly tuberculous, who, while they had tubercle bacilli in the sputum, were not in an excessively debilitated condition. In the second group of cases, out of 20 there were 17 positive and three negative reactions, the latter being from two patients suffering from tuberculous peritonitis and from one with incipient pulmonary tuberculosis. In the group of the pretuberculous, in whom radioscopic and other subsidiary signs were suspicious, there was a very high percentage of positive results equal to 95 per cent. These results, which confirm those of Punch and Gosse, point to the conclusion that the Bordet-Gengou reaction is generally negative in healthy individuals and generally positive in the tuberculous, and is of great value in the early diagnosis of tuberculosis.

CANCER AND DIET.

Our leading article on Diet and Cancer has elicited from Dr. Copeman a letter which appeared in last week's Lancet. Dr. Copeman there disclaims the sensational statements which have been attributed to him by the lay press as having been made by him in Liverpool. He says that the use of his dietary has "not been found to exert any specific differential effect in the growth of the tumour, as had originally been hoped might prove to be the case, and that consequently the cure of cancer was not in question, the methods being at most palliative only." We welcome the disclaimer, but still find it difficult to reconcile this modest claim with Dr. Copeman's suggestion that the rationing in war time should have been the cause of the recorded diminution in mortality from cancer, or with the claim that his treatment increases the expectation of life. As regards our criticism that Dr. Copeman did not submit his results to his peers, we are informed that the meeting to which Dr. Copeman referred in his letter was a private one. It follows therefore that neither the substance of his communication at that meeting, nor any comment which may or may not have been made upon it, are available for the guidance of the medical profession as a whole, or for that of the general public.

COÖPERATION.

Our advertisement pages this week record a sound example of the value of coöperation between the editorial and business sides of a great journal, for while we are in other places alluding with, we trust, justifiable satisfaction to the attainment of a Centenary, we notice that many of the houses which are advertising in our columns are as venerable as ourselves, and several have a longer pedigree. The centennial course of the Morison Lectures is being delivered this year before the Royal College of Physicians of Edinburgh, the British Medical Association can trace its real foundation 90 years backwards, while the firm of Allen and Hanburys has a pedigree of over 200 years. Messrs. Offord and Son have been established more than a century, the Royal Medical Benevolent Fund has been at work for nearly 90 years, while Messrs. J. and A. Churchill are only two years short of their Centenary. The house of Cassell is but ten years younger, and Messrs. Duncan, Flockhart and Co. have been well-known agents for the supply of anæsthetics since their discovery, and the house of Martindale arrives at its jubilee this very year. Claimants to seniority ranging back for long if lesser periods are too many to be enumerated, but apart from the valuable information contained in the advertisements, the reader will find interesting notes on medical and pharmacological history in the *dossiers* of many of the firms. To the enterprise and support of many of these firms it has been due in large measure that we have been able for 100 years to keep faith with our readers. It may be observed that, as in the case of the editorial columns, so in the case of the advertisement pages, there is a perpetual stream of new effort. The old firms do not rely upon their antiquity for their success, for necessity, if nothing else compels them to keep pace with younger efforts directed sometimes generally and sometimes along special lines undreamt of at the foundation of The Lancet. These efforts change from day to day with the science of medicine which, in the words of the old French proverb, changes always, but always remains true to the same objectives.

EXPEDITION OF THE LONDON SCHOOL OF TROPICAL MEDICINE TO SAMOA.

A research expedition, under the direction of Dr. Patrick Buxton, is to leave on or about Nov. 15th for Samoa, where a number of problems of tropical medicine will be studied. The expedition will be absent for two years. The main object of study will be the practical prevention of filariasis and its associated diseases, the most striking of which is undoubtedly elephantiasis. The present is the fifth expedition which has been despatched to study this subject since the foundation of the School. The first was undertaken by Dr. G. C. Low[1] to the West Indies, and definitely established the exact mode of transmission of the filaria through the mosquito. This observer also shed a great deal of light upon the pathology of filariasis. Shortly after this the existence of a special variety of filaria worm, apparently confined to the Pacific Islands, became known. This led to the despatch of an expedition in 1910 under Dr. P. H. Bahr,[2] the results of which were definitely to establish the fact that the filaria of the Pacific inhabited by preference the lymphatic glands, that it produced embryos which circulated in equal numbers in the blood-stream both by day and by night, and differed in this respect from the nocturnal periodic habit of the filaria of other parts of the tropics. The intermediary host of this filaria was found to be a peculiar mosquito known as *Stegomyia pseudoscutellaris* (now termed *Aedes variagatus*), a day-biting insect, one which is peculiar to the Pacific Islands and which occurs there in very great numbers. No morphological differences could be ascertained to exist between the adult filaria worm removed at operation or autopsy from the Fijians and similar ones indigenous to India, China, and elsewhere (*F. bancrofti*). In 1921 a Commission under Prof. R. T. Leiper and Dr. J. Anderson studied the same question in British Guiana, where the typical *F. bancrofti* is abundant, and the report of this expedition is now awaited. To elucidate further these interesting problems regarding the Pacific filaria, Dr. F. W. O'Connor [3] was despatched to the Western Pacific, making the second expedition to that area, and visited the Allice, Tokelau, and Samoan Islands in 1921 and 1922. The result of his very extensive travels was to demonstrate more fully the correlation between the distribution of filariasis in the Pacific and that of its intermediary host, the stegomyia, for wherever this insect abounds filariasis is common. It was further ascertained that this insect is definitely connected with the presence of the coconut palm, abounding under its shadow and breeding in the disused coconut shells which are cast aside in the making of copra. It also thrives in any collection of water in the hollow trunks of the coconut palm. Further evidence was adduced that the filaria of the Pacific may be, in a pathological sense at any rate, distinguished from the true *F. bancrofti*. The close connexion between ankylostomiasis, filariasis, and tuberculosis, all of which diseases are combining to exterminate many of the Polynesian races, was definitely established. It is now proposed to extend the results of these various expeditions still further, and to demonstrate the possibility of prevention of filariasis by measures directed against the intermediary host, the stegomyia. All attempts so far at finding a drug sufficiently potent to kill off the embryo filariæ in the blood-stream have failed, nor does there seem to be any possibility of the discovery of such a drug in the future.

[3] O'Connor, F. W.: Researches in the Western Pacific. Research Memoirs of the London School of Tropical Medicine, vol. iv.

The prevention of this disease is not such a difficult matter as might at first appear to be the case. It is proposed to make an actual experiment on the same lines as are familiar in the prevention of malaria and yellow fever. It is known that the insect and the disease it carries are specially common on small coral atolls, of which many are to be found in the Samoan group. On these islets the growth of vegetation composed of thick masses of coconut palms may be only some 50 or 60 yards in diameter. It is quite possible that by cutting out the undergrowth, by burning the disused coconut shells, by filling in possible breeding-places in the trees, and by providing the inhabitants with a proper water-supply, the numbers of this very specialised insect may be so reduced in a few months' time as to become negligible; and it follows that if this insect can be exterminated the disease will die out with it. Although there are five other species of mosquito which bite man in these islands, yet this is the only species (and all the others have been tried) which will act as an efficient intermediary host of the filaria. It is into this and other cognate problems that Dr. Buxton will inquire. He will be assisted in all probability by one or more newly qualified medical men from New Zealand, and it is hoped that in this way an interest for the study of tropical diseases will be kindled in the medical schools of that progressive Dominion, for it is only recently that New Zealand has been saddled with the responsibility of tropical possessions in the mandatory territory of the Samoan group. There are other important researches which the expedition will undertake, notably those concerning the physiology of the normal European body under tropical conditions, and the regulation of the formation and loss of body heat will be investigated by means of the kata-thermometer and other specialised instruments. It is hoped also to undertake researches on the biochemistry of the blood and urine during acclimatisation in the tropics, and this is a subject upon which very little information exists.

THE Royal Medical Benevolent Fund has received from Sir Thomas Barlow a donation of £300, which has been invested for the benefit of the annuitants.

AT the Royal Society of Medicine, in the Section of Therapeutics and Pharmacology, on Oct. 9th, at 4.30 P.M., there will be a discussion on the Use of Insulin in General Practice, at which the first speakers will be Prof. Hugh Maclean, Dr. George Graham, and Prof. J. J. R. Macleod.

INSTALLATION OF NEW X RAY APPARATUS IN ELGIN. At the quarterly meeting of the managers of Dr. Gray's Hospital, Elgin, it was decided to have a new X ray apparatus installed. Mr. J. F. Cumming, of Aberlour, one of the directors of the hospital, offered to defray the whole expense of the new X ray plant.

DONATIONS AND BEQUESTS.—Under the will of the late Mrs. Gertrude Alice Rees, of West Hill-road, Bournemouth, the testatrix left £5000 on trust for her husband for life with remainder to the Liverpool Royal Infirmary to be used for the convalescent treatment of patients from that hospital in memory of her late son, Alexander Armstrong Rees, M.D., R.A.M.C.—By will the late Mrs. Susanna M. Taylor, of Putney, left among other bequests £500 to the Putney Hospital, £100 to St. Columbia's Hospital, £50 to the Cottage Convalescent Home, Wimbledon, and 10s. each to the patients at the time of her death at the Royal Hospital for Incurables, "as a little pocket money."

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XXXIX.

THE TREATMENT OF FLAT-FOOT.

THE worst symptoms of flat-foot occur in feet which are not flat; the term "flat-foot," as commonly used, covers also those conditions of foot strain and flattening foot which precede the fully developed flat-foot. Symptoms of flat-foot arise when the muscles which act on the foot fail to resist the crushing down action of the body-weight. The foot itself, apart from its muscles, is not designed to support the body-weight, and, when pressure is made upon it from above, it is crushed down, flattened, and passively abducted and everted. The function of the muscles is to prevent this passive displacement and distortion by a continuous tonic reflex contraction of the adductors and invertors, which is but a part of the postural reflex which maintains the upright position of the body as a whole. Any condition, local or general, which interferes with this muscular action causes strain and flattening of the foot. The commonest cause of flat-foot in adults is prolonged standing or over-use of the foot, whereby the muscles are exhausted; almost as common is flat-foot in individuals suffering from general loss of tone from various causes. Local injury also temporarily abolishes the reflex activity of the muscles, so that traumatic flat-foot is a common sequel of sprained ankle, Pott's fracture, &c. In most cases faulty boots and shoes contribute to the mechanical strain, and are often the direct cause of the flat-foot. The effect of crushing down the foot depends upon the type of foot, and there are very many different types. In general, the severity of the symptoms is in proportion to the resistance offered. The low-arched supple foot, with freely mobile joints and atonic muscles, flattens easily, without resistance and without pain, while the high-arched thick-set or sturdy foot offers great resistance and distortion of its joints causes great pain, which is felt long before any flattening is apparent.

In most cases flat-foot develops gradually; for a long time the foot remains supple, and its natural form can be easily restored by gentle manipulation or by voluntary effort. But sooner or later the foot becomes fixed or partly fixed by secondary changes in and around the joints. At first the loss of mobility is due to "adhesions" or contracture of ligaments on the outer side of the joints, but in old-standing cases the foot becomes rigid from osteo-arthritic changes. When flat-foot develops rapidly, the pain from the rapid distortion of the joints may give rise to reflex spasm of all the muscles acting on the foot; this spasm is most pronounced in the peronei muscles, and the foot is held rigidly abducted and everted.

The only real cure is to restore to the muscles their normal postural activity, though the ideal result is not always attainable in practice. Some individuals are unsuited to muscular re-education, and in many cases circumstances, such as continued over-use of the foot, make the attempt hopeless. One must, then, be content to relieve the foot from mechanical strain, so that the patient may walk in comfort.

Preliminary Measures.

Before curative treatment can be attempted it is necessary (1) that the foot shall be capable of being brought into its proper position by the action of its own muscles, and (2) that the foot and its muscles be relieved from mechanical strain. (1) When the foot is still supple the patient can invert it and draw up the arch. When it is stiff from adhesions or shortening of the ligaments it should be thoroughly manipulated under an anæsthetic, after which it should be firmly strapped or bandaged for a few days, and active movements should be begun as soon as possible; it is not necessary to fix it in plaster-of-Paris. No attempt should be made to mobilise old-standing or inveterate flat-feet or those that are rigid from osteo-arthritis. (2) When the foot can be brought into its natural position it is necessary to retain that position by a suitable arrangement of the boot or shoe until the normal muscular action is restored. This is in practice the most important part of the treatment, for foot strain is thereby relieved, and, whether or not true restoration of function follows, the patient is at least rescued from pain and disfigurement. It would seem superfluous to say that the boot should fit the foot were it not that the majority of people wear boots and shoes that are too big for them. The boot should hold the foot, not merely cover it.

Men's Shoes.—The usual type of man's boot or shoe, when new, has an almost flat inner sole (insole) which in no way corresponds to the shape of the sole of the foot. When a normal active foot walks in such a boot or shoe it tends to make a bed for itself by depressing the insole at the main points of pressure—namely, under the heel, along the outer border, and beneath the heads of all the metatarsal bones. To this pressure of the foot upon the insole there is, of course, a corresponding counter-pressure of the insole upon the foot. An exhausted or inactive foot is unable to resist this pressure, and, instead of moulding the insole to its own contour, it becomes itself flattened to conform to the surface upon which it rests. Further, the waist of the boot between the heel and the tread may give way when the insole becomes actually concave upwards, and the strain on the foot is correspondingly increased. The obvious way to prevent, and also to correct, this flattening effect of the boot or shoe is to make the insole to conform to the shape of the sole of the foot. The foot, indeed, should stand on its own footprint, exaggerated if need be, and will then drop into its natural position even though the muscles are relaxed. This is a question of balance rather than support; it is entirely unnatural for the arch of the foot to be propped up by a rigid unyielding support. The "moulded insole" is the best means of keeping the supple flat-foot in its proper position during use. It is made by taking the last upon which the boot or shoe is to be made and building it up with leather at the points where the insole is to be depressed—namely, along the outer border and across the tread to the ball of the big toe. The instep is thus by contrast made higher, and it may be raised still more by cutting away the last, which must be made to correspond to the particular type of foot. A foot with a high arch requires a greater depression under the tread, and a higher instep, than a foot with a medium or low arch. The height of the heel is not just a matter of choice; the correct height is found by placing a straight edge approximately at a tangent to the tread of the last, and noting its distance from the heel. The greater the depression under the ball of the foot, the higher the heel. In many cases it is an advantage to raise somewhat the inner side of the heel, so as to throw the posterior part of the foot outwards, but no wedge should be put on the inner side of the sole, for in walking the foot must "take off" from the big toe, which must, therefore, be dropped and not raised from the ground. Finally, the insole must have a firm foundation to rest upon or the waist of the boot may be broken. A stout leather "shank piece" should be inserted between the soles from the heel—not under it—to the tread.

Women's Shoes.—The usual type of woman's shoe has a heel two inches or more in height, and the sole slopes abruptly from the back of the heel to the tread, so that the foot tends to slide down an inclined plane surface on to the heads of the metatarsal bones. The sole is flexible and yielding, so that when pressure is put on it from above, the waist of the shoe is bent downwards, the toe rises, and the heel is tilted upwards and backwards. A normal active foot rests upon such a shoe only at the heel and tread. When, however, muscular action is deficient, the foot comes to rest more and more upon the insole of the shoe, and breaks it down in the middle; further, owing to lack of lateral stability, the high narrow heel causes a great strain to come on the foot in the abducted position. The moulded insole for a woman's shoe should be constructed on the lines already described, but the shoe need not be unsightly. The sole must be rather thicker than is usual in a woman's shoe, and the necessary shank piece in the waist adds a little to the thickness and weight. A heel of 1¾ or 2 in. must often be allowed. Indeed, owing to her manner of walking—which is quite different from that of a man—a woman requires a deep bed under the tread, and this in itself necessitates a relatively high heel. The "upper" may be of any material fancied; it is quite possible to construct a presentable shoe which is yet surgically correct. A central point, though not strictly correct, may be conceded; hallux valgus, except in its slighter degrees, is not due to pointed shoes, but to flat-foot, and if the shoe is in other respects correctly made, the central toe does no great harm.

The chief difficulties in practice are the inconvenience and expense of having to have every pair of boots and shoes specially made, and the difficulty of getting the ordinary bootmaker to make them as required. In the slighter degrees of painless flat-foot, especially in children, one may be content to raise the inner side of the heel and put a loose raised insole under the foot. But in flat-foot of any severity, and when there is pain, it is essential to have the boots or shoes correctly made.

Muscular Re-education.

When the foot is kept in its proper position and the strain has been relieved, the natural function of walking will in many cases provide all the exercise necessary. The patient should be told to get some spring into the gait, and to use the feet actively. An additional exercise is to stand with the feet together and sharply invert them so as to stand on their outer borders. This movement brings the postural muscles into action and draws up the arch of the foot. It is the only exercise that need be done. The patient should be told to practise it whenever he is standing. Its object is to re-educate a reflex; and a simple exercise done continually and habitually is far more effective than a series of exercises done on set occasions. No attempt should be made to correct old-standing, inveterate, or rigid flat-foot. The boot or shoe should be an easy fit, the insole should be made quite flat like the foot, and the heel should be low. If there is pain beneath the heads of the metatarsal bones, some soft material such as spongy rubber should be put under the tread.

Spasmodic Flat-foot.—The best treatment for peroneal spasm is to ignore it. It is a self-limiting condition which may persist for months, though not indefinitely. The foot, regardless of its present form, should be put into a boot constructed for its normal condition with a high arch and a deep bed under the heads of the metatarsal bones. The patient should be shown how to pull the foot inwards and relax the spasm, which he will gradually find himself able to do. It is unnecessary to divide the peroneal tendons, to crush the nerve, or to manipulate and immobilise the foot. The spasm eventually goes under the simple treatment outlined and the foot returns to its natural position.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

A Ministry of Health.

THE question of the establishment of a Ministry of Health in the Free State has lately attracted some public attention. On Sept. 19th the Council of the Irish Nurses' and Midwives' Union at its annual congress unanimously passed a resolution authorising its executive to take whatever steps lay in its power to organise a united demand by nursing organisations, and other bodies interested in health, that a Ministry of Health should be established. The following day in Dail Earann, Sir James Craig, in a debate dealing with the appointment of ministers, regretted that nothing had been said about the establishment of a Ministry for Public Health. He was not one to urge the multiplication of ministries, but surely the health of the people was of more importance than fisheries. The health of the country was in a very serious position. If a special ministry could not be set up he suggested the setting up within the Local Government Department of a department of public health, with a secretary or some other person responsible in the Dail. He regretted that Mr. Ernest Blythe was giving up the Ministry of Local Government. Mr. Blythe, in reply, said that there could be no question of having a department for local government and a separate department for public health at the same time. The Local Government Department was almost entirely concerned with matters of public health. It was really a matter of choosing a name, for it was intended to give the Local Government Department the real substance of a Ministry of Public Health, with one or two functions added to it for the sake of convenience. The position is by no means satisfactory. If the Department of Local Government is to be in truth a Ministry of Health, it should be so called, that both the Minister and his permanent staff might know where their real duties lie. At the present time the Ministry deals with many matters not remotely connected with health, such as the maintenance of roads and the control of fairs and markets. On the other hand, some important matters of health, such as the inspection of factories and the department of vital statistics, are not under its control.

PARIS.

(FROM OUR OWN CORRESPONDENTS.)

Cancer Congress at Strasbourg.

THE summer vacation, now ending, was at least partially filled for those engaged in scientific medicine by a series of important Congresses, of which the Cancer Congress held at Strasbourg at the end of July was among the more important. The Congress was presided over by Prof. Pierre Delbet, was opened by Mr. Paul Strauss, Minister of Hygiene, and included among its members many distinguished foreigners. Of the three main subjects dealt with at the Congress, the first was the experimental production of cancer. Prof. J. Fibiger (Copenhagen) discussed the Spiroptera-cancer discovered by him in 1907. This growth is produced by a parasite living in the upper part of the digestive tract of rats and mice, with the cockroach as intermediate host, the insect being infected by ingestion of the fæces of these animals. Fibiger believes that the cancrogenous action is due to the secretion of the parasites themselves in a soil predisposed to cancer. The nature of the predisposition depends on factors affecting the entire organism together with the cells at whose expense the cancer grows. Prof. K. Itchikawa (Sapporo, Japan) gave a fully documented résumé of his researches into the experimental production of cancer with tar. The simple chemical and physical irritation of tar applied repeatedly and continuously to the internal aspect of a rabbit's ear produces cancer of the epithelial cells in the same way as the action of the parasites described by Fibiger. Dr. J. A. Murray (London) read a remarkable paper on Primary and Secondary Resistance to the Production of Cancer.[1] Dr. A. Leitch (London) contributed a communication on the specificity of various cancer-producing agents, interpreting cellular cancerisation as a continuous and prolonged manifestation of the normal action of tissue repair. The second subject of discussion, the general reaction of the organism in connexion with cancer, was dealt with by Dr. Rubens-Duval (Paris) and Dr. W. H. Woglom (New York). The third subject, the treatment by radium and X rays of spino-cellular epitheliomas of the skin and mouth, was discussed by Profs. A. Bayet (Brussels) and Cl. Régaud (Paris).

Other Vacation Congresses.

The conference of French alienists and neurologists held at Besançon in August was remarkable for an attack by Dr. Hesnard on Freud's theory. Hesnard maintained that the cause of nervous and mental diseases was only related to sex in exceptional instances, being far more commonly connected with poverty, business failure, thwarted ambition, or physical infirmity. He also criticised psycho-analysis as a means of diagnosis, holding that the method is uncertain, and may induce hysterical symptoms or further derange patients already unbalanced. From a therapeutic standpoint, he considered that the numerous cases whose ætiology included an organic factor were incurable by this method, and that when psycho-analysis gave results these were no better than those obtained by any other psycho-therapeutic method. Dr. Courban attributed the success of psycho-analysis in Anglo-Saxon countries to the mystery with which sexual matters are surrounded by Protestant morality.

The Fourth International Congress of Neurology, held at the Salpêtrière, Paris, in the summer vacation, was attended by many foreign delegates, among them Sir James Purves-Stewart and Dr. G. Riddoch.

The following Congresses will shortly be held in Paris at the Faculty of Medicine: Twenty-third Congress of Urology, beginning on Oct. 10th, President, Prof. André; Thirty-second Congress of Surgery, Oct. 8th to 13th; Congress of Orthopædics, Oct. 12th; Annual Congress of Hygiene, Oct. 22nd to 26th.

A Home for Doctors in France.

A party of members of the French medical profession recently assembled at Valenton (Seine-et-Oise) in the Château de Charmilles, which has been established as a home or retreat for aged and infirm medical men, and it has been christened "La Maison du Médicin." The home owes its origin to an association which was founded in 1908 with headquarters in No. 9, Rue Astorg, Paris, whose object was to establish and control one or more homes where aged, infirm, sick, or needy

medical men might be cared for. The Association does not aim at making financial profit; the home is maintained by donations and by subscriptions from members of the Doctors Home Association. Residents in the home contribute towards the expenses of their keep, but before the war the income from this source was never more than Fr.12,000 (£480) per annum. From the start all the best known medical men of France have given their support to the work of the Association. The principles of making a charge, however small, for board and lodging helps to preserve a sense of independence, yet while the principle is one of "paying guests," no really destitute case is ever turned away. In recent years the grounds of the home have been extended and they now cover over 15 acres. Many of the boarders spend their time working in the gardens or the orchards, and during the winter theatrical performances and concerts are held. English medical men are invited to visit the home at Valenton.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Vienna Medical Faculty: Weekly Discussions.

ACTING on a suggestion thrown out by a few members of the Vienna University, the medical faculty organised last year a series of discussions with a view to attracting the attention of the profession to the latest achievements in the art of medicine. By providing post-graduate opportunities for the interchange of ideas and opinions this scheme has, within one year, become an important asset to the entire medical profession of Vienna. The discussions are held on Monday evenings. Admission is free, no membership is required, and any medical man is welcome. Any practitioner may suggest in writing to the secretary of the faculty a subject on which he desires information. The questions submitted are handed over to leading specialists, each of whom volunteers to deliver a lecture on a particular subject. Generally a week is allowed for preparation. At the meetings anyone may put questions to the lecturers. The discussions last two hours and are well attended, the average number present being about 50. An interesting feature is the eagerness with which the older members of the profession take an active part in the proceedings of the "Seminar-abend," as these evening meetings are called. It speaks well for the institution that it has already served as a model for similar developments in various university towns of Germany. That the earnest spirit underlying such work is already bearing fruit is shown in the rising scientific standard and public reputation of the profession.

A School of Nursing for Medical Men.

The Vienna University Clinic for Children inaugurated a few months ago a totally new departure in the medical curriculum—a school of nursing for doctors. It is a well-known fact that very often the practitioner has to order this or that measure in the course of the management of a serious case of illness in a child, but the mother or even the nurse does not always know how to carry out his instructions in the most effective and satisfactory way. Often, too, doctor and mother are at cross purposes, through sheer ignorance on the doctor's part of domestic exigencies. To such considerations we owe the opening of the above-mentioned school in the Pirquet Clinic. The plan of work is as follows: Four physicians of the clinic—house physicians of the hospital—are entrusted with the entire care of the ward. They have to do all the work usually resting on the shoulders of the nurses or "sisters," in managing a sick child. This task is best illustrated by the following programme of the duties. At 5.45 A.M. the doctors take over the charge of the ward. From that time till 7.15 A.M. they must wash, bathe, and tidy the children (or babies, as the case may be). The next 30 minutes the breakfast is served by them to the patients. Up till 9 A.M. the preparation of the patients for the morning round of the professor, marking the temperature charts, giving medicine or other treatment prescribed, superintending feeding the sucklings. 9–10 A.M., morning round. 10 A.M. to 12 noon, examination of newcomers, dismissal of old patients, temperature taking, feeding of babies. 12 noon to 1 P.M., serving out of dinner (or lunch), feeding of the older children. 1–3 P.M., nursing work on the new patients, feeding of babies. 3–4 P.M., preparation for the evening round, tea for the older children. 4–5 P.M., evening round. 5–6.30 P.M., temperature taking, feeding of the babies, supper for the older patients. 6.30–7.30 P.M., filling in of the charts and records of each patient. At 7.30 P.M., the day service terminates. The night duties are at present discharged by a nurse, but will in future also fall to the lot of the physicians. Physicians attached to this ward must serve a term of two months. It is hoped that in the future all house physicians of the Pirquet Clinic will be obliged to undergo training in the school. Not a few of the duties hitherto regarded as purely "feminine," such as shaking the bed-quilts, spreading the table-cloths, or the administration of an enema, are rather embarrassing at first, but the young doctor soon gets used to it. In order to ensure variety of experience in nursing duties, the children are left in this school "for doctors only" for a few days. All new patients must pass through this ward before they are distributed in the other wards of the clinic, so that in these few days the doctor has the opportunity of studying a larger number of differing types of patient than was formerly possible. Many useful "tips" in feeding, holding, and calming children are learned and insight into the little patients' minds is gained—a point of paramount importance for the future task of the practitioner. The ward personnel includes two women, a maid for purely household work, and a nurse whose duty it is to initiate the "essentially masculine" students into what has too long been considered woman's province. The idea of this "school of nursing" has been received with great approval by the profession generally, and it is contemplated that the new curriculum for the medical student which is now under consideration and which will necessitate a year of practical work before giving the right to practise, might also include a course in this school.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

Numbers of the Medical Profession in Hungary.

ACCORDING to a report issued by the Hungarian Medical Association there are at present 4489 physicians practising in Hungary. Of these, 2012 practise in Budapest. As the population of the country is something over 8,000,000, the ratio of physicians to population is too high. The number of physicians is decreasing on an average by 225 a year; the number of medical students in the country in 1922–23 was 6751. The Medical Association is now advising parents not to encourage their children to enter this overcrowded profession. The distribution of doctors is very uneven; in towns the ratio of doctors to population is 1 in 350–500, but numerous small provincial towns have no resident medical men at all.

The Scientific and Commonwealth Universities.

At the opening of the present session of the Scientific University of Budapest the number of registered students was greatly reduced as compared with that of previous years, particularly in the Faculties of Medicine and Philosophy. Many students are prevented from taking up the study of medicine by the expense involved. The Minister of Public Instruction permitted the registration of no more than 500 students in the Faculty of Law, but the "Commonwealth" University admitted 1400 students without objection from the Minister. The Scientific University does not even now recognise the Faculties of the

Commonwealth University, and the latter is not represented in the Council of the Scientific University. The Council has several times requested the Minister to establish a proportion between the numbers of students in the two Universities. The teachers in the Commonwealth University have not even the rank of lecturers, while those in the Scientific University are all qualified University professors. The Council of the Scientific University also complain that the Minister neglects the upkeep of the University library, despite its European reputation, allocating only 200,000 kronen (about £30) for the purpose during the year, whilst other libraries received 40–50 million kronen.

An Unjustified Accusation.

Dr. Ödön Nemeth, professor of mental diseases at the University of Budapest, was lately accused by a lawyer of ill-treating his (the lawyer's) brother, an army captain, while the latter was under his care in an observation ward of a mental hospital. The charge included neglect of attention to the patient's cleanliness, clothing and food, and brutal handling, with disastrous effects upon his general health. A full investigation of the facts proved that all the indictments originated with lay visitors, who made misstatements to the lawyer. It also transpired that the latter had attempted to influence the doctor with a view to removing any impediment to the captain's promotion to higher rank, and consequent entitlement to a higher pension. Dr. Nemeth brought numerous witnesses to prove that his diagnosis was correct, and was corroborated by Prof. Moravcsik, the leading forensic expert in Hungary. The treatment was shown to be the most modern and humane treatment available. The prosecuting lawyer acknowledged that his information was derived from unreliable sources, and apologised to the professor. The court was not satisfied with the apology, although the professor accepted it ; a charge of falsely accusing a public official will shortly be preferred against the lawyer.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

A Case of Pneumo-peritoneum.

AN interesting case was lately shown to the Berlin Medical Society by Dr. Mosler. A man of 63 years had been run over by a butcher's cart 15 years ago. He was in hospital for five months, the case being diagnosed as a fracture of several ribs of the left side. After the accident the abdomen had always been much inflated. Radiographic examination has now revealed a quantity of air present in the abdomen, by which the liver and the spleen were displaced downwards and the diaphragm pressed upwards. The cause of this pneumo-peritoneum was obviously a rupture of the lung and of the diaphragm which had not healed. Through the fistula of the lung and the fissure in the diaphragm air was continuously inhaled into the abdomen, to be absorbed in part during the night. Notwithstanding the gravity of the injury the man suffered little and was able to work.

Regulation of Medical Fees.

As already explained in these columns, the Government is authorised by law to fix the fees in cases where they have not been agreed upon between the patient and his medical attendant and to issue official regulations in the matter. Recently sanction has been given to additional payment in accordance with the value of the currency, the last increase being to 20,000 per cent. The Leipziger Verband, the great union of the German medical profession, has protested against the amount of this increase, pointing out that the cost of living had increased by 40,000 per cent. The Government stated that the fees had been raised in the same ratio as the salary of the Government officials, whereupon the Leipziger Verband, in a letter addressed to the Government Medical Department, answered that there are many differences between Government officials and medical men to the disadvantage of the latter. The officials receive their salaries one month in advance, whilst the medical men, especially those engaged in club practice, receive their fee at the end of the month or even at the end of a quarter. The officials have no professional expenses for instruments, telephone, assistance, consulting-rooms, &c., which reduce the income by about 50 per cent. ; moreover, Government officials are entitled to a pension for themselves and their dependents, whilst a medical man must try to save funds for the support of his family, a matter quite impossible under the present circumstances. Government officials residing in the occupied district receive, moreover, an extra remuneration, whilst the fees of medical men are the same there as in unoccupied Germany, notwithstanding the cost of living is several times higher there. The medical profession will, as the Leipziger Verband states, be rapidly reduced to the starvation level if its members do not get more assistance from the authorities in their struggle of life.

New First-Aid Huts in Berlin.

A private society of advertising contractors lately started a system of first-aid by constructing small huts in busy thoroughfares to contain a transportable stretcher, medicines for emergencies, dressing materials, splints, &c. In cases of sunstroke the patient may be laid in the shady hut until he is conveyed to a hospital. The hut can be opened by breaking a pane, under which the key is placed. A few of the huts—of which the society intends to build about ten—have been put up already. The expenses will be entirely met by the advertisements on the walls of the huts.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

Government Control of Hospitals and Charities.

ON July 1st, 1923, came into force the Act relating to hospitals and charities passed by the Legislative Assembly of the State of Victoria in December, 1922, which, as far as can be ascertained, is the most comprehensive legislative scheme of the kind in existence. The object is the central control of all charitable agencies in the State. Some of the salient features of the Act are, that every charitable institution and every benevolent society or organisation in the State must register by approval of a Charities Board ; that no person or authority can appeal for, nor accept contributions on behalf of, any charitable movement unless so registered. The Board has the power to close any unnecessary hospital or charity, to amalgamate institutions which are serving the same purpose in close proximity, to determine the use to which any institution may be put, and to resume any land which is considered essential for hospital purposes.

Post-graduate Teaching in Melbourne.

There is marked enthusiasm and activity in post-graduate teaching in Melbourne. The work is arranged by a representative committee under whose auspices Dr. J. F. Wilkinson has just completed a series of lectures on the treatment of gastric disorders and diabetes. The lecturer has recently returned from an extended tour of most of the special hospitals (English and American) doing this work. Judging from his views, especially those on the treatment of diabetes, Dr. Wilkinson spent more time in America than in England. The lectures were a masterly résumé of all the modern work, and referred especially to the new insulin treatment, the early results of which he had seen in America.

The Hobart Hospital, Tasmania.

Trouble arose at the Hobart Hospital (Tasmania) some years ago over an announcement by the Government that the hospitals were open to anyone caring to seek admission. After protest the honorary visiting staff resigned, and the Government made a contract with one, Victor Richard Ratten, to act as surgeon-superintendent. It was subsequently discovered that Ratten had been registered in virtue of a certificate of what appeared to be a bogus American night college, thereupon the Government passed a special measure to legalise this registration. It was felt that the state of affairs at this hospital was to the disadvantage both of the medical profession and the hospital public; therefore, on the reappointment of the surgeon-superintendent falling due, an attempt was made to arrange a conference between the B.M.A. and the board of management of the hospital. This conference was arranged, but before it could take place Ratten was reappointed by the board of management as the surgeon-superintendent with limited right of private practice. The matter will now drop unless the Government intervenes, and it is unlikely that the local medical profession will accept any appointment at this hospital in the future.

Insulin in Australia.

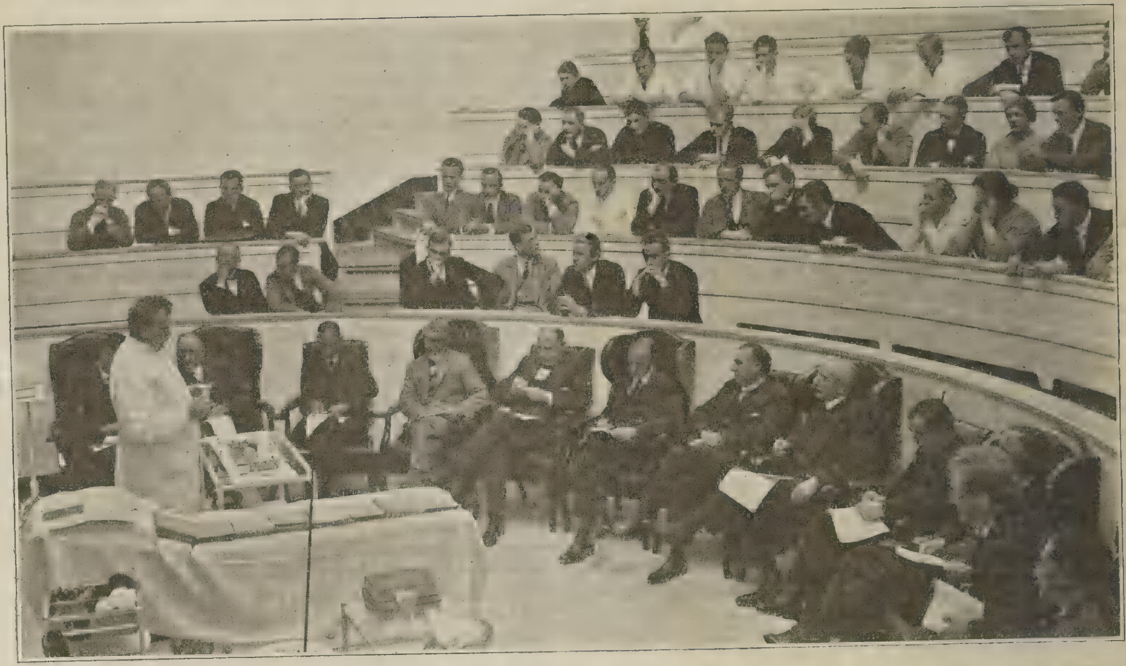
The Commonwealth Serum Institute has undertaken the manufacture of insulin, but up to the present it is only available in limited quantities and to special hospitals. The manufacture is being carried out under great difficulties, and it is not likely that it will be produced in any large amounts at present.

The Australian Medical Congress.

The arrangements for the Congress to be held in Melbourne in November are well advanced. A special feature will be a discussion on the early diagnosis of tubercle, in which all sections are taking part. Other subjects for general discussion are exophthalmic goitre and renal insufficiency.

BRITISH SURGEONS IN DENMARK.

THE recent visit of a party of British surgeons to Denmark, under the ægis of Prof. W. Thelwall Thomas, afforded a welcome opportunity to many of them to make the acquaintance for the first time of Prof. Thorkild Rovsing, the most distinguished of the Scandinavian surgeons. Rovsing's many and great achievements have been the outcome of a combination of qualities, one at least of which is rare. He has always shown an inveterate distrust of traditional teachings and text-book orthodoxy, and his work has not only consisted of building up but also of breaking down and clearing away much rubbish. His special field has for many years been abdominal surgery, and his treatise on this subject has been a standard work for more than a generation. For the past 30 years he has devoted special attention to the subject of gall-stones, and the part of this work which has already been published shows him in his most characteristic attitude—that of the iconoclast attacking false gods. It is anticipated that the final chapter of this work will be published in a few weeks; it challenges many of the accepted theories as to the genesis and development of gall-stones.



Prof. Thorkild Rovsing demonstrating to British surgeons and Danish students at the Danish State Hospital. The visitors included Mr. John Anderson, Mr. Arthur Henry Burgess, Mr. Arthur Cooke, Mr. Ernest F. Finch, Prof. E. W. Hey Groves, Mr. Robert Ernest Kelly, Sir John Lynn-Thomas, Mr. Keith W. Monsarrat, Mr. John Morley, Mr. H. Herbert Rayner, Mr. Graham Scales Simpson, Prof. W. Thelwall Thomas, Mr. G. Grey Turner, and Mr. Henry Wade, some of whom are easily recognisable in this photograph.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

To be Surg. Lieuts. (D.): R. M. Finlayson, G. G. Cruikshank, T. Hunt, L. M. Hughes, L. B. Osborne, C. J. Finnigan, R. J. M. Andrews, and A. W. Wallace.

ROYAL ARMY MEDICAL CORPS.

Maj. and Bt. Lt.-Col. R. A. Bryden relinquishes the actg. rank of Lt.-Col.

Maj. A. H. McN. Mitchell retires on ret. pay and is granted the rank of Lt.-Col.

Maj. H. C. Todd retires receiving a gratuity.

Capt. M. P. Power relinquishes the actg. rank of Maj.

Capt. W. B. Allen, V.C., retires, receiving a gratuity and is granted the rank of Maj.

RESERVE OF OFFICERS.

Army Dental Corps.—Capt. E. D. Batty, late Gen. List to be Capt.

ROYAL AIR FORCE.

L. P. McCullagh is granted a short-service commission as a Flying Officer.

A. W. Comber is granted a temporary commission as Flight Lt.

ST. MARY'S HOSPITAL MEDICAL SCHOOL: POST-GRADUATE COURSE.

THE week-end post-graduate course at St. Mary's Hospital was well attended, between 100 and 150 medical men from all parts of the country being present at the lectures and demonstrations. There can be no doubt that the course, which was instituted last year is a popular one, for the increase of attendances this year was noticeable. The adoption of some similar scheme by other teaching hospitals might go far to meet the reproach that London schools have little to offer the student when once he has left the school.

On Sept. 29th the first lecture was delivered by Mr. D. C. L. FITZWILLIAMS, the subject being

Early Diagnosis of Cancer of the Breast.

Mr. Fitzwilliams emphasised the importance of immediate pathological investigation in any case where there was the slightest suspicion of malignancy in a swelling of the breast. Malignancy in its earliest stages—just when it was of the utmost importance to detect it—showed no signs or symptoms. At the most, certain features, such as absence of pain, might give some inkling of the condition, but as a rule diagnosis by clinical methods was impossible until many months had elapsed. Records showed that there was a 2½ to 1 chance of all swellings in the breast being malignant. Surgeons were ready to open the abdomen on much less definite possibilities than that; therefore, he urged, every lump in the breast which was not obviously innocent should be considered malignant until by exploratory incision and removal of part of the growth the pathologist was able to make his pronouncement. This examination held out hopes of effective treatment, as cancer in the breast was much more favourably situated for operation than in any other organ. At the same time, he pointed out the difficulty of obtaining the patient's consent in every case to this preliminary operation.

Mr. T. G. STEVENS gave an illuminating discourse on

Prolapse.

Although the condition was called "prolapsus uteri," he showed that the uterus itself had nothing to do with the cause of it. It was really a "sacro-pubic hernia," due to two factors: (1) injuries to the levator ani muscle, and (2) stretching of the transverse cervical ligaments. The cause of these two conditions was invariably labour, and in the vast majority of cases instrumental labour. In applying forceps the head was pulled down, but the cervix was pulled down also with the result that the transverse cervical bands were stretched, often beyond recovery. The patient might show no signs at the time, but eventually prolapse resulted It was not often recognised, he pointed out, that the earliest symptoms of prolapse were those of enteroptosis, such as palpitation and various abdominal disturbances. Rupture of the perineum in itself did not in the least dispose to prolapse; the important factor was damage to the levator ani. Chronic constipation and chronic bronchitic cough were subsidiary factors. In passing, Mr. Stevens mentioned that in a prolapsed uterus, though subjected to friction, the development of malignant growths was almost unknown. The only efficacious treatment for prolapse was operation, or rather a series of operations—amputation of the elongated cervix, anterior and posterior colporrhaphy and perineorrhaphy. This afforded an absolute cure; pessaries might give comfort, but they only predisposed to further prolapse.

Mr. MAYNARD SMITH, discussing

Chronic Pain in the Right Side of the Abdomen,

differentiated between chronic appendicitis and recurrent attacks of acute appendicitis. In the former case the patient showed the symptoms of intestinal toxæmia. There were two chief causes of pain in the right abdomen: (1) chronic infection of the large intestine, and (2) visceroptosis, nor were these mutually exclusive. The first was often associated with bad teeth, and in the patient's stools definite bacteria, not normally present, were found. The best treatment was the Plombières method of lavage, intestinal antiseptics, and careful diet. Visceroptosis was constantly diagnosed as chronic appendicitis, but the removal of the appendix did not effect a cure. The symptoms were gas-distended cæcum with pain on pressure and frequently mobility of the kidney. On examination the cæcum formed a dependent bag, loose and soggy, which was very characteristic. The only effective treatment was excision of kinks, hemicolectomy, or colopexy; short-circuiting of the ileum into the sigmoid was of no value. Other causes of right-sided pain were: (1) Commencing hydronephrosis, shown by X ray of barium injected into pelvis and ureter. (2) Gastric ulcer; here the pains were always definitely associated with food. The fractional test-meal was of great help in diagnosis. (3) Gall-stones; the pain was not definitely associated with food. (4) In women, chronic pyosalpinx and salpingitis of the right side. Many illustrative cases were quoted, and some excellent X ray plates were shown.

Chronic Rheumatic Toxœmia.

Sir WILLIAM WILLCOX pointed out that in cases of arthritis every system of the body should be searched for other evidence of toxæmia, the exciting cause of which was almost certainly an infection. A recent visit to France had provided the speaker with some insight into the different aspects of chronic arthritis that received special attention in different countries. In France the metabolic side of the treatment was uppermost, the diet of arthritics receiving careful consideration, whereas the condition of the mouths and teeth of many such patients in hospital in Paris was neglected. In other respects, however, we had much to learn from our colleagues abroad. Fibrositis, now known to be an objective condition demonstrable by skilled palpation and by radiography, was treated in France by injections of a substance known as lipiodal, which contained 20 per cent. iodine. In this country great advance had been made recently in the use of massage for this condition, with the idea of opening up the lymphatic channels and removing the depositions which were responsible for the fibrositis. Electrical treatment and the application of heat were also useful in certain cases, and some patients derived most benefit from the application of a linseed poultice after painting with iodine. As to the treatment of chronic rheumatic arthritis or rheumatic toxæmia, a focal infection must be searched for and, if possible, eradicated before resort was had to drugs, though the temptation to continue removing foci of infection until there was hardly any part of the patient left must be avoided. As to other methods, reliance should not be placed on one alone, but a judicious combination of many methods, such as vaccine therapy, drugs, Plombières treatment, or spa treatment led to very considerable improvement even in severe cases. Intestinal antiseptics had given no striking results when used by themselves; a mixture of guaiacol carbonate gr. x. and aspirin gr. iii. was sometimes of value. Iodine in collosol form or still better in the form of the French tincture (3 or 4 drops, increasing to 8 or 10 in ℥ ii. water one hour after meals) had given some relief in his hands, and thyroid in small doses (gr. i. t.d.s.) was sometimes useful, and measures directed to the improvement of the general health and spirits of the patient should be tried.

Cœliac Disease.

According to Dr. REGINALD MILLER cœliac disease, usually considered rare, is in fact about as common as abdominal tuberculosis in children. Mal-absorption of fat is the basis of the disease, and the cardinal feature is the discomfort and unhappiness of the untreated child, and the remarkable improvement in its general well-being, appetite, and growth following judicious treatment. The characteristics of the the disease, said Dr. Miller, were the big proportion of fat in the stools, which were large, pale, unformed, offensive, and frequent; a white diarrhœa was often present. Other signs were a large abdomen without any distinguishable mass, anorexia, occasional fever, diminished growth amounting in some cases to cœliac infantilism, and pallor. Dr. Miller demonstrated cases and outlined the course of the disease, which begins during the second year of life and does not clear up without treatment, though at the age of 13 to 15 the capacity for fat digestion tends to improve spontaneously. Mild cases were recognisable in which the excess of fatty acids appeared in the stools mainly in the form of soaps. The stools in these cases were large, coloured, formed, and not particularly offensive. The principle adopted was to start the child on a diet as nearly as possible fat free, to ascertain the percentage of fat in the stools on this diet, and to resist all parental attempts to add fat for a considerable period. Dr. Miller suggested as a skeleton diet for breakfast: fish, egg or tongue, bread (no butter), and syrup or honey, tea with skimmed milk or cocoatina. At 11 A.M. bovril and rusks. Midday, fish, chicken or lean meat, clear jellies, stewed fruit, boiled rice made with skim milk, or Victoria sandwich, with water to drink. Tea a normal meal, without butter, and a supper of skim milk. When fat was increased very gradually, a scrape of butter was the first step, and then puddings made with ordinary milk. Bile-salts might be given; the improvement in the child should be gauged by its general condition and by height rather than by weight.

On Sept. 30th Dr. C. M. Wilson spoke on the

Investigation of Dyspepsia.

He prefaced his lecture by emphasising the difficulties confronting the general practitioner in making a complete investigation of all cases of dyspepsia. A complete investigation involved a bismuth meal and a fractional test-meal as well as careful clinical examination, but obviously this was not feasible in every case. He warned his audience, however, against the error of failing to perform these tests in a certain number of cases where investigation was definitely indicated, an error frequently made owing to lack of time and opportunity. Dyspepsias could be broadly classified into two groups: Those due to spasm of the pylorus caused frequently by some reflex stimulation such as that from the gall-bladder or appendix, and those cases where there was true obstruction or stenosis of pylorus. Dyspepsia might be due to gastric ulcer, duodenal ulcer, gall-stones, or chronic appendix. In doubtful cases X rays and fractional test-meals threw light on the diagnosis of all these when weighed with the clinical evidence, though even with complete investigation it must be acknowledged that the diagnosis of duodenal ulcer was frequently found to have been made erroneously when put to the proof by laparotomy. In the speaker's opinion it was rash to operate on cases of dyspepsia supposed to be due to a chronic appendix unless an acute attack had occurred. He regarded a complete investigation to be necessary in the case of a primary dyspepsia in middle life not relieved by treatment and accompanied by loss of strength and appetite where carcinoma was suspected. Although there might be no filling defect in the X ray, carcinoma should not be entirely excluded; the presence of an achlorhydria in the fractional test-meal and absence of chlorides would help to elucidate the diagnosis. In cases of functional dyspepsia it was important to remember that there were two groups, broadly speaking: (*a*) Those with a dread of cancer or ulcer, when the complete investigation would effect a cure by the reassurance given; (*b*) the hopelessly introspective type of patient who would be made considerably worse by having his attention yet more concentrated on his alimentary system. Errors of secretion and loss of motility were largely responsible for many cases of functional dyspepsia.

Dr. Wilson proceeded to consider the

Treatment of Diabetes by Insulin.

This lecture was particularly valuable from the point of view of the practitioner in its clarification of the use of insulin. Dr. Wilson divided glycosuria, differentiated by the glucose-tolerance test, into renal diabetes—where no treatment is needed—and diabetes mellitus. In diabetes mellitus those cases were classified into Group I. where patients by dieting can be made sugar-free and can keep so on a living diet. These were subdivided into (*a*) patients whose blood-sugar can also be reduced to normal by dieting, and here there was no need for insulin; (*b*) patients in whom the blood-sugar is still raised though the urine is sugar-free. In Group II., in spite of dieting, the urine does not become sugar-free and patients cannot tolerate a living diet. Types (*b*) of Group I. and Group II. cases need insulin. But while the only hope of a patient in Group II. would appear to be to take insulin for the rest of his days, Dr. Wilson held out the hope that by resting the islands of Langerhans by administration of insulin in type (*b*) cases where structural damage had not yet occurred, recovery might subsequently take place. Especially in the acute type of case between 20–30 years of age was the outlook hopeful. He queried whether the reason for failures among patients treated by the Allen diet might not be the fact that in the past, although the urine was sugar-free, the blood-sugar might have remained high. Other cases where insulin would be indicated were those to whom it was necessary to administer an anæsthetic, and patients threatened with diabetic coma.

(*To be concluded.*)

Obituary.

Sir JOHN HALLIDAY CROOM, M.D., LL.D., F.R.C.S., F.R.C.P. Edin.,

EMERITUS PROFESSOR OF MIDWIFERY, UNIVERSITY OF EDINBURGH.

Sir Halliday Croom, who two years ago retired from his professorship of midwifery at Edinburgh, died on Sept. 27th in his seventy-seventh year. Born at Sanquhar, the son of the Rev. David Croom, minister of the Lauriston-place United Free Church in Edinburgh, he was educated at the High School and at the University of Edinburgh, and later studied in London and Paris. The whole of his professional life was devoted to his specialty, midwifery and the diseases of women. On his return to Edinburgh he became assistant to the professor of medicine in the University, and in 1870 was appointed assistant to the professor of midwifery (Prof. A. R. Simpson) and a university tutor, becoming F.R.C.S. Edin. in 1873. For seven years Halliday Croom conducted large tutorial classes in midwifery and gynæcology, and in 1878 was appointed lecturer in obstetrics and gynæcology in the Edinburgh School of Medicine. Elected F.R.C.P. Edin. in 1880, he graduated M.D. two years later. From 1886 to 1901 he had charge of the gynæcological wards in the Royal Infirmary as assistant to the professor of gynæcology and obstetrics. In 1905 he succeeded Sir Alexander Simpson in the chair of midwifery, from which he retired in 1921. Halliday Croom was knighted in 1902, and in the same year was elected president of the British Gynæcological Society. He was the author of several works dealing with his specialty, and was examiner therein in the Royal College and University of Edinburgh, and in the Universities of Oxford and St. Andrews. He was awarded the honorary LL.D. Edin. and M.D. Dublin, and the honorary Fellowship of the American, Belgian, and Leipzig Gynæcological Societies. He was in 1903 President of the Royal College of Surgeons of Edinburgh.

In 1875 Halliday Croom married Anna Isabella, daughter of Mr. Daniel Walker, His Majesty's Inspector of Factories for Scotland. He leaves a son, Dr. David Halliday Croom, well known in Edinburgh, and three daughters.

We hope to publish later a fuller notice of the career of this great teacher and clinician.

Congratulatory Messages.

Many letters, written in unofficial capacities, have been received congratulating us on our Centenary, with permission to publish them in full or part. This permission is here utilised with a deep sense of gratitude.

FOR its century of devoted service to the common health and to the well-being of the medical profession, THE LANCET has made the nation its debtor. As in private duty bound, I acknowledge gratefully its notable efforts to promote the passing of the Medical Acts, and the establishment and expansion of the General Council of Medical Education and Registration, with all the public benefits that have thence been derived.

DONALD MACALISTER,
President, General Medical Council.

The Centenary of THE LANCET—a notable milestone n medical journalism—affords the profession a welcome opportunity of expressing a timely appreciaion of the wholesome influence that it has so constantly exerted. The early and vigorous, sometimes ndeed even dramatic, action of THE LANCET in xposing hospital nepotism and abuses, in organising he profession, in the establishment of the General Medical Council, and in the advocacy of national unds for hospitals and other charitable objects will lways be gratefully remembered as matters of medical istory. But there are other important though less striking ways in which it is constantly directing and aising the standard of medical practice, ethics, and iterature, and the high character of medical ournalism in this country owes much to the wise and independent inspiration of THE LANCET.

HUMPHRY ROLLESTON,
President, Royal College of Physicians of London.

My first literary effort was in the form of a letter o THE LANCET in 1881. I was a student at the ime, and naturally astonished at the consideration f the Editor. When I started practice in 1884, a etired physician gave me the first 30 bound volumes f THE LANCET to assist in filling my bookshelves. I read those volumes with the keenest interest and elish. The slashing articles on nepotism, the fearess criticisms of hospital surgeons, and the ability f Thomas Wakley to conduct his own defence in is libel suits excited my admiration.

I have read the journal regularly throughout my rofessional life. It wins respect by fairness, and onsideration of the youngest as well as the oldest members of the medical profession. It is watchful ver the humdrum daily incidents of general practice s well as the highest scientific affairs of medicine s a whole. The leaders and reviews are to-day rank and fair; interest in the welfare of the profesion is unlimited, and the journal has an instinctive oathing of quackery and jobbery.

In style, production, editorial skill, and judgment THE LANCET, to my mind, is the best medical journal n the world.

JOHN BLAND-SUTTON,
President, Royal College of Surgeons of England.

The Centenary of THE LANCET is, indeed, an epochmaking event in medical journalism, "the dividing of time." All the world over, through a long series of ears, your paper has represented an advanced policy n medical education, in sanitary science, and in reventive medicine. Many substantial and fareaching reforms have followed directly upon your ane and persistent advocacy, and in this way THE ANCET has proved itself not only an invaluable urrent exponent of medicine proper, but also of its wise application to the betterment of man's estate nd its good governance.

But something more may, I think, be truthfully aid. THE LANCET has been remarkably scientific in its insight and apprehension, and studiously moderate and judicial in its exposition. It has, of course, often been vigorous in expression and critical in judgment, but there has been a disinterestedness, stability, courtesy, and dignity in its pronouncements which has reflected the best medical thought and spirit of the time. It has thus faithfully represented the *science* as well as the *art* of medicine.

So it comes about that the substance of your reward for a hundred years of achievement is the continued loyalty, confidence, and appreciation of innumerable medical practitioners, officers in all branches of the public health service, scientific workers, and even patients, in this country and in many parts of the world.

GEORGE NEWMAN,
Chief Medical Officer, Ministry of Health.

Hearty congratulations to THE LANCET on attaining its Centenary. I know of no medical journal which has attained such celebrity, and which meets the wants of English-speaking medical men better. That THE LANCET may still continue to flourish and to instruct is my earnest hope.

JOSEPH CHAMBERS, C.B., C.M.G.,
Medical Director-General, Navy.

On the occasion of the Centenary of THE LANCET will you permit me to offer you my sincere congratulations, and to express the confident hope that the Journal, over which you preside so ably, may maintain throughout its second century the high repute acquired in its first?

You will doubtless receive many letters assuring you of the esteem in which THE LANCET is held by the profession, but I may perhaps be allowed to refer specially to the debt which the Medical Departments of the Services owe to it. Those whom duty calls from station to station, and often to service overseas in isolated posts, would indeed feel themselves divorced from medical progress were it not for the weekly study of THE LANCET or some sister Journal, and such as make this study a habit need never fear that they are getting "rusty" or out of date.

In spite of the wide extension of medical experience and research, and the spread of specialisation, the selection and distribution of material in THE LANCET is so well balanced that one rarely reads a number without acquiring information which one feels to be of real and personal value. The specialist must, it is true, consult in addition his own journals, but, were he to limit his reading to those, he would soon become narrow in his outlook, and his progress would be hampered in many directions.

The R.A.M. Corps owes THE LANCET a special debt in respect of its patriotic action during the war in sparing no effort to put on record, in convenient form, the knowledge, new or scattered, which might be of service to those responsible for the care of the sick and wounded. This was of inestimable value, and was a direct and very potent factor in obtaining the results which are, I think, generally acknowledged to have been excellent.

THE LANCET has always supported the best interests of the Services, and has aided them in their own efforts to maintain their efficiency and professional standing at a high level. I can assure you that it has many readers in these Services who are most grateful to it, and who would desire to join me in congratulating it on its Centenary, and in wishing it continued prosperity.

W. B. LEISHMAN, Lieut.-General,
Director-General, Army Medical Department.

May I send you my personal congratulations on the Centenary of THE LANCET, which is recognised in India, as at home, as one of the greatest of the medical journals, and express my hope that it may continue for another hundred years to represent all that is best in British medicine?

JOSEPH B. SMITH,
President, India Office Medical Board.

Il y a cent ans, la presse médicale ne comptait dans chaque pays qu'un petit nombre d'organes. Depuis, ce nombre s'est considerablement multiplié. Mais THE LANCET, entre tous, a toujours maintenu son rang honorable et est resté l'un des plus réputés des journaux britanniques et même des journaux du monde entier.

C'est un grand honneur pour la médecine française de figurer régulièrement dans les colonnes de ce journal estimé, sous la rubrique du French Supplement. En son nom, nous adressons à la rédaction de THE LANCET nos très vifs remerciements et nos meilleurs vœux pour la prospérité de la toujours jeune centenaire.

CH. ACHARD,
Professeur à l'Université de Paris.

CH. FLANDIN,
Médecin des Hôpitaux de Paris.

Under the guidance of the Wakleys THE LANCET established in medicine its great tradition. Change in editorship or ownership has not at any period introduced variation in policy. To-day, as throughout our generation, in ethics as well as in medicine, THE LANCET stands for whatsoever is good and sound. We trust it and feel secure. When it inaugurates or supports any movement we know it has the highest interests of the profession at heart. Long may it continue to represent and to give to the world the best in British medicine.

J. GEORGE ADAMI,
Vice-Chancellor, the University of Liverpool.

THE LANCET on its centenary carries me back to times long ago. From THE LANCET blew one of the breezes which wafted me into the profession of medicine. Of my five medical uncles (including a "great" one), two lived near my home; and I rejoiced in the old-fashioned surgery, and ransacked the aromatic jars and drawers, some of them still bearing quaint old labels, such as "mummy powder," "thorn of the Unicorn," "crabs eyes," and so on. Amid these provocative stores lay dusty files of the early LANCET; some rather fusty volumes dating from its very birth. At the age of 9 or 10 for many an hour I would sit quiet with these volumes on my lap—their columns at that time half grown, rather sallow in complexion, and not very clear in print. Yet I recall the fascination of the figured woodcuts of the mystic convolutions of the human brain; and, more intelligibly, the interesting mechanism of the hip-joint; but the old Adam, born in us all, found a still livelier joy in the pungent controversies in which during those years the journal was engaged. There was a foretaste of battle in the editor's very name; and in those generations literary brickbats were hurled about by commentators and editors with a hearty pugnacity unknown in our milder day. Mr. Wakley was not a bit afraid even of the majestic Royal Society or of the noble Marquess, its President. As the Chicken remarked of Mr. Dombey, "Stiff a cove as he was, it was within the resources of science to double him up with a well-directed blow in the waistcoat." Wakley vigorously attacked nepotism, buckram plausibilities in high places, and bumbledoms. He defended the club doctor, and fought with remarkable foresight for public health and the prevention of disease. In particular he was revolted by the unchecked, almost unheeded, ravages of syphilis, and stripped its disguises from a malady which seems then to have been even more rampant than in our own time, although its neurological manifestations were then unrecognised.

I am told that the deep-sea fisherman keeps his codfish alive in a salt-water cistern in the boat, so that they may come fresh to market; but these fishes, in this respect, quite like human beings, when they find themselves in snug quarters are apt to take their ease; and so after all come to table with stale flesh. To keep them alert, therefore, the fisherman puts with them in the tank a "catfish," as I understand, a very irascible animal, whose ways are disturbing to the repose of higher circles, and the codfish are so continually exercised by this pertinacious foe that their flesh is kept in good condition. No parable has four legs; I would not compare Mr. Wakley with this malevolent fish, but I do say that the inhuman torpor of the eighteenth century was then far from dispelled or much disturbed, and that a fearless reformer was sadly needed. As Wakley himself said, he did not intend to refrain from remonstrance or even vituperation until in the affairs to which I have alluded, as also in food adulteration, in the maladministration of military medicine, in the Poor-law, in lunacy, and in the crudities of judicial psychology, sorely needed reforms were at least set on foot. The easy classes were, of course, furious, but on cursorily turning over the old volumes again I find after all the editor's vituperations and sarcasms, if biting enough, were less naughty than I had supposed. Not only so, but THE LANCET's main work, the shedding of daylight on hospital management and teaching, the publications of lectures by learned physicians and surgeons, and of scientific papers, was indeed an inestimable boon to the general practitioner and to the public.

If in later years THE LANCET has been able to work in an air of more amenity and on amicable terms with officials, publicists, and journalists, it has been the better able still to advocate the vital reforms fought for in its early days by its fathers, and to contend with more good temper but no less fervour and sincerity for causes as entirely farsighted and beneficent. For the ideals of the early LANCET ar as yet far from their accomplishment.

CLIFFORD ALLBUTT,
Regius Professor of Physic, University of Cambridge.

For the long period of 100 years THE LANCET has been the weekly exponent of new knowledge gained in the science and art of British medicine. Moreover, it has maintained without flinching th necessity for the highest standard of character conduct, and attainment in the whole medica profession, and has contended without fear or favou for the mutual and reciprocal obligations of th doctor and the public. For these very real service to the body-politic THE LANCET deserves heart recognition at its forthcoming Centenary.

THOMAS BARLOW,
Late President, Royal College of Physicians of London.

Please accept my sincere and warm congratulation on the Centenary of THE LANCET. It seems to m that it has not only maintained its ancient reputa tion, but has advanced and progressed as its year have increased. All good wishes for its futur career.

ANTHONY A. BOWLBY,
Past President, Royal College of Surgeons, England.

Best congratulations on the Centenary of TH LANCET. It has fought good fights for high profes sional standards and sane legislation.

WATSON CHEYNE,
Late President, Royal College of Surgeons of England.

I send you my heartiest congratulations on th hundredth anniversary of the founding of TH LANCET. The journal has had a most benefici effect on the progress of medicine during that lo period, and I may also add that its influence h done much to advance both medical education a raise the general status of the medical profession.

W. S. CHURCH,
Late President, Royal College of Physicians of London.

The celebration of your Centenary brings to mi how greatly the nation in general, and the medic profession in particular, are in your debt. You ha ever espoused learning, and stood for a high standa of professional achievement and public servic Your criticism has been fearless, yet always co structive and encouraging. Your influence has be on the side of liberty and professional unity. In the larger fields of conquest and usefulness which lie before it, the medical profession will find in you the same vision, courage, and single-minded purpose. We owe you much; we rejoice in your strength and wish you God speed.

DAWSON OF PENN,
President, Medical Society of London.

All who care for the progress of medicine will unite in congratulating THE LANCET upon this centennial birthday, and they will wish that its fine tradition and influence, so well deserved and secured, may be maintained throughout the second century upon which it now enters. THE LANCET has rendered great services of many kinds to the best interests of the public and of the profession, and of these the history of medical education and practice will always preserve the record. Not least among these has been its constant aid to the advancement of the medical sciences in all their parts, and to the diffusion of new knowledge for the service of all. Posterity will be born in heavy debt to THE LANCET. The best wish for THE LANCET at this Centenary is that the debt already incurred may be heavily increased.

WALTER FLETCHER,
Secretary, Medical Research Council.

Good wine needs no bush, and a journal which has attained to its hundredth birthday must be held to have justified itself to the full. Since the publication of that slim first volume THE LANCET has had to adapt itself to many changes of outlook in matters medical, and to shifting journalistic fashions. Dramatic criticisms and chess problems no longer figure in its pages, nor do we find descriptions of highly "genteel surgical audiences," composed of "gentlemen of cultivated manners and good education" who hang upon the words of a great surgeon—a description somewhat discounted by the account, furnished to a later number by a correspondent from Edinburgh, of the half hour preceding the entry of the lecturer. The edge of THE LANCET was very keen in those days, and it cut deeply.

A somewhat truculent youth followed by a maturity of increasing esteem, and now in mellow age, the journal shows no signs of diminished vigour. It afforded a vehicle for the views and aims of that great reformer who was its founder and first editor, and has ever been in the forefront of the battle for progress; as witness, the part which it played in securing medical registration, better methods of appointment of members of hospital staffs, and many other reforms. Nor has it ever failed to carry out its original purpose—namely, to bring the teaching of the medical schools to the knowledge of the profession at large. THE LANCET goes all over the world, and has ever been ready to publish work in scientific medicine, even when such work deals with subjects which make no wide appeal. If only for this reason the journal has earned the gratitude of all who have at heart the advancement of medical science and the progress of the healing art.

The whole profession will join in congratulation to the proprietors, and to the present Editor upon the occasion of its Centenary, and in the hope that its second century may still further enhance its usefulness and fame.

ARCHIBALD E. GARROD,
Regius Professor of Medicine, University of Oxford.

Amongst odd volumes left me by Marcus Beck is an octavo, the third edition of Vol. I. of THE LANCET, 1823–4, published in 1826. Once it belonged to Thomas Hunter, Esq., Surgeon *Grampus*, Royal Seamen's Hospital Ship, and afterwards to Tom Cooke, above whose name is written in a female hand, "Fanny Hunter, 1828—when this you see remember me when I am far away."

Occasionally I browse amongst the lectures of Abernethy and Astley Cooper, or gloat over some of its "hot stuff." For it was a pugnacious age. In these earliest years of its existence, the Editor says: "It is true we have been loaded with the vituperation of the vulgar and ignorant, but this is a kind of tax which everyone who aims at the public good must be content to pay"; and we may add that he was well able to pay with interest.

The Introduction, dated Dec. 8th, 1825, summarises the reasons for starting THE LANCET and the successes already attained. The primary purpose was *generally* of "communicating to the profession the earliest notice of every passing event in the medical and surgical world; and *especially* of cultivating the vast and hitherto unexplored field of inquiry which the great hospitals of the metropolis presented to our view." Another was the publication of lectures. A modicum of "polite literature and news of the day" had at first been introduced, but this was soon crowded out by the unexpected mass of medical material available. After two years the vigorous predecessors of the present vigorous Editor boasted of the instantaneous success of their labours. "Imbecility, in many instances, was banished from our hospitals, abuses were corrected, improvements multiplied, and a new and salutary impulse was imparted to the medical schools of the metropolis. The publication of lectures and hospital cases formed a new and distinguished feature in the annals of science, and, as might have been anticipated, was vehemently opposed by the parties most likely to suffer from the innovation."

This is the spirit, mellowed more and more by time, that has inspired THE LANCET during the wonderful first century of its existence. It is true that, as its mascot, the lancet is now only found in museums, we no longer look for cutting satire or pungent phrases in our weekly number; but we are sure to find the latest news, a full report of new scientific inquiries, healthy criticism in the correspondence columns, inspiring and instructive leading articles, and the restrained though merciless exposure of abuses.

It shows no sign of senility. Therefore, though I have long since hung my lyre upon the wall, I still read my LANCET regularly, feeling sure that it will always be up to date, and that it will continue to exert a wholesome influence upon the profession as it has consistently done in the past.

RICKMAN J. GODLEE,
Late President, Royal College of Surgeons of England.

Considering the multitude of periodicals it is rare for one to reach its Centenary. ALL the medical profession are proud that their paper, THE LANCET, should have done this, but it has an additional honour, for during the whole of the hundred years it has been an example of what a really first-class journal should be. Its very name is appropriate, for it has exposed numberless abuses and has always striven to improve the health of the community. THE LANCET Analytical Sanitary Commission led to Acts of Parliament protecting consumers from adulteration of food, and many other examples might be given of this newspaper's work for the good of the nation. Likewise it has continually upheld everything which might enhance the standing of the medical profession; quite at random I looked at a number of THE LANCET of 80 years ago and found the editor maintaining that medicine is a profession, not a trade. It has throughout a century been fearless both in its exposure of charlatans, quacks, and advertisers, and in its support of really good medical work. The position which our profession holds in the estimation of the public is largely due to THE LANCET. Those responsible for its conduct have ever kept in view the desire of its founder to disseminate medical knowledge. They have believed that, as Johnson said, newspapers are "rivulets of intelligence, which are continually trickling among us, which everyone may catch, and of which everyone partakes." The original articles and the clinical lectures and reports, which have appeared in THE LANCET, form a complete history of medicine and the allied sciences for a hundred years. Everyone must wish its second century to be exactly like its first and hope that, when this island is excavated many thousands of years hence, the explorers will come across volumes of THE LANCET.

W. HALE-WHITE,
President of the Royal Society of Medicine.

I cannot let slip the opportunity of congratulating you on the remarkable success of THE LANCET in recent years. During the 17 years that I was editor of *Brain*, I watched with admiration the way in which the journal met the many difficult situations which arose, and I am always grateful for the interest that has been shown in the progress of modern neurology.

HENRY HEAD,
Consulting Physician, London Hospital.

I am anxious to join with the large number of your friends who will send you congratulations upon the Centenary of your journal. Of the many important contributions to the progress and to the dignity of our profession made by THE LANCET, through the attitude it has adopted at times of crisis, others can testify more specifically than I can. But I wish to add a word of praise for the invariably high standard that THE LANCET has maintained in regard to the scientific articles appearing in its columns. As the premier journal for giving expression to advances in clinical and pathological work, it has been of the utmost service to medicine to know that this high standard could be relied upon at all times. The columns of THE LANCET have always seemed to me to mirror the best in the history of medical progress.

THOMAS HORDER,
Physician, St. Bartholomew's Hospital.

The Centenary of THE LANCET is indeed a great occasion. What a wonderful record of work it represents! It has always stood for what is best in our profession. May it long continue its honourable and enlightened career!

ROBERT JONES,
Consulting Orthopædic Surgeon, Royal Infirmary, Liverpool.

I have been a weekly debtor to THE LANCET for considerably more than 30 years and hope my account may continue for years yet. As I glance over the list of contents with each fresh issue, with a sneaking hope that there may not be so many columns that must be read—if one would keep abreast with all forward medical movements—I am usually disappointed; each number contains articles that one cannot afford to let pass unnoted.

There cannot be a shadow of doubt that the medical press of a country is a sure index to the state of medicine in that country; nor is it less true that a country's place in the van of medical progress depends to a very large extent on the light and leading given by its medical press. In these respects British medical men may regard THE LANCET with pride.

THE LANCET has always welcomed to its pages the younger men who had something new to say—something which, although remote from practice, yet went to laying the art of healing on a foundation of sound knowledge. In this respect, too, I am deeply indebted to THE LANCET, as so many other men have been. I wish THE LANCET a continued prosperity.

ARTHUR KEITH,
Conservator, Hunterian Museum, Royal College of Surgeons of England.

It is impossible for me to let the Centenary of THE LANCET go by unnoticed. The paper has done wonderful work for the profession, thanks to the way in which its objects have been preserved and its career directed for so long. I trust that it may flourish for many years to come.

W. ARBUTHNOT LANE,
Consulting Surgeon, Guy's Hospital.

I congratulate you and your colleagues upon the Centenary of THE LANCET. It is satisfactory to find that the journal still pursues a course characterised by the virility of youth, guided by the wisdom of a hundred years' experience. The debt of medicine to the journal cannot be computed, and it is not possible to realise what British medicine would be without THE LANCET. Wishing your famous journal a continued career of usefulness and fame,

J. MACKENZIE,
Director, Institute Clinical Research, St. Andrews.

The passage of a century at once excites the imagination, appeals to the memory, and demands respect. The advent of the Centenary of THE LANCET furnishes its readers with the opportunity for indulgence in each of these directions. A review of the volumes may well excite speculation as to the future, while at the same time it recalls the history of perhaps the most splendid and fruitful period in the science of medicine, covering as it does the rise and development of preventive medicine, the practical application of the great discoveries in the domain of pathology, and the advance of surgery to an extent surpassing the wildest dreams of our ancestors. Of only less interest is the continuous record of the changes and developments of professional policy and ethics, and the host of personal memories which are aroused. In each and all these directions THE LANCET may proudly claim that it has taken a part the value and influence of which cannot be over-estimated.

Success such as has attended the conduct of THE LANCET and the international repute which it enjoys call for congratulation rather than praise, while it demands the gratitude of those whose work the journal has set forth and disseminated; yet, it must be stated that the paper is a possession of which the profession of this country is justly proud. A glance at the early history shows that the path struck out by the projectors of THE LANCET was not always easy and straightforward, but the storms and difficulties which have had to be encountered by successive Editors have been met with such a degree of skill and judgment that the confidence and respect of its readers have never been endangered. The early career of the journal considered in relation to the position it holds to-day awakens a comparison between its life-history and that of many of our greatest public men. Launched in a stormy sea, and renouncing novel and advanced views not palatable to all, it steadily grew in public estimation and influence until it reached the position of eminence it still occupies to-day. It starts upon its second century with the good wishes and gratitude of its readers, and a hearty desire that the second century may be still more successful than the first.

G. H. MAKINS,
Late President, Royal College of Surgeons of England.

It is an easy matter to celebrate the foundation, the continuity of existence, and the uninterrupted progress for a 100 years of any institution or organisation, by a festival dinner or other convivial entertainment; but when the occasion is the centenary anniversary of a great journal like THE LANCET something more is necessary to do it suitable honour and justice, and to give proper expression to a hope that the future career may prove to be not less successful than its past history. This something is the confidence with which it can be truthfully asserted that the projects with which THE LANCET set out at its foundation, good as they were in themselves, have in great degree been realised and accomplished; that with its growth in years the growth in results has been proportionate or even greater; and that those to whom has been entrusted the duty of carrying on the work of the journal have loyally adhered to and developed the ideals of its Founder. Such a review can only be made after careful personal examination of the pages of THE LANCET itself from its commencement, or by the perusal of a good historical account such as Sprigge's "Life and Times of Thomas Wakley," supplemented by a personal acquaintance with THE LANCET subsequent to the period at which the history terminated.

In 1823 when THE LANCET first appeared, one medical journal at least, the *London Medical and Physical Journal*, had been in existence for 24 years. It ran from 1799 to 1833, and then ceased to exist. Another medical journal, the *London Medical and Surgical Spectator*, first published in 1808–09, very soon came to an end. Whether any other medical journal had preceded THE LANCET I do not know, but at any rate the Founder and Editor of that journal was able to state in the Preface to No. 1, Volume I., the following: "There has not hitherto existed a work which would convey to the public, and to distant practitioners as well as to students in medicine and surgery, reports of the Metropolitan Hospital lectures." Such information it was declared to be the intention of the new work to supply in the most ample manner; and in addition to lectures it was proposed to give under the head, "Medical and Surgical Intelligence," a correct description of all the important cases that may occur, whether in England or on any part of the civilised Continent. It was also announced in the same preface that it was intended to convey to country practitioners, and to medical and surgical practitioners in London who were unable to attend personally at the hospitals, as well as to the numerous classes of students whether here or in distant universities, the means of ascertaining the progress of medical science. In the sixth number of THE LANCET was started under the title "Hospital Reports" a regular series of records of the proceedings in hospital practice, and this was long continued under the heading, "A Mirror of Hospital Practice."

Other objects which the Editor set out to accomplish were improvements in the education, discipline, and the social life and habits of medical students; to afford opportunities for the rank-and-file of general practitioners to get and remain in intellectual touch with the leaders and teachers of the profession; and to suppress the various abuses in the several departments of the profession, in colleges, hospitals, and medical schools, which existed prior to, and for some time after, the birth of THE LANCET. There are many still living who for the last half or more of the centenary have been regular readers of THE LANCET, and who can of their own knowledge bear witness to the courage and perseverance with which these reforms have been accomplished, and to the constancy and thoroughness with which other developments have been effected. THE LANCET provides liberally for the publication of hospital lectures, collegiate lectures, the clinical reports of cases, the progress in tropical medicine and in public health, as well as of post-graduate lectures and clinical and laboratory notes. It furnishes helpful commentaries on the collateral sciences, and on new experimental and scientific investigations. Its leading articles, annotations, and critical commentaries are very useful and instructive. It keeps its readers informed on medical and surgical literature through its well-balanced reviews of books and other new publications. It keeps an eye on the medical services at home and abroad, and, so far as it can, furthers the interests and well-being of their members. It discusses judiciously questions concerning preliminary and intermediate education and the medical curriculum in general; and it affords the parents of intending medical students (and the students themselves) great assistance in ascertaining what is required and expected of their sons on entering the study of medicine; it has also been of outstanding use to the General Medical Council itself in more ways than one. And, not the least of its services, THE LANCET makes known the merits of medical institutions, and the development, organisation, and coöperation of professional associations and societies. It gives publicity to the needs of medical charities, and in a variety of ways renders useful information to the public as well as to the profession itself. This enumeration, by no means complete, of conspicuous features of THE LANCET, supplies a wide basis upon which to found a pæan of congratulation for a great record of excellent work admirably done.

HENRY MORRIS,
Past President, Royal College of Surgeons of England.

THE LANCET is the friend of every man in the profession. The story of its early years of struggle against privileges which were bought rather than earned, against "hole and corner" surgery, against all the heavy abuses under which our profession suffered a century ago, has been told by its present Editor in a volume of the deepest interest. Wakley was responsible for the publication of the lectures of Abernethy, and of Sir Astley Cooper. Every author who is fortunate enough to secure a place in the pages of THE LANCET to-day will proudly regard himself as in the direct literary succession to these men, among the greatest our country has produced. Wakley stood for individual and professional rights against the encroachments made on them by those within and without our ranks. Idols were shattered and at the moment no little harm was done. But the permanent good was immeasurably greater than the harm. From that day to the present time the journal has taken the leading part in this country in upholding the duties and responsibilities of the profession in its relation to the public, and no less in informing the public of the professional view of matters concerning the welfare of the people.

Regarded either as a purely medical journal, or as an instrument for the instruction both of the profession and the public upon questions that closely affect them both, THE LANCET stands, I am convinced, foremost in the estimation of us all. Long may it remain so.

BERKELEY MOYNIHAN,
Senior Vice-President, Royal College of Surgeons of England.

Having been associated with THE LANCET for many years as contributor and reader, and having had the last Editor of the name of Wakley as a personal friend and contemporary, I hope I may not be regarded as presumptuous if I ask permission to unite my congratulations, no doubt with very many others, on the occasion of the Centenary of that journal, which has so pre-eminently represented the medical profession and reflected its best ideals both personal and social. Its utility in stabilising medical knowledge carries with it an indebtedness on the part of the public which cannot well be estimated.

Long may it continue the good work.

DAV. NICOLSON,
Lord Chancellor's Visitor in Lunacy (retired).

Au moment où THE LANCET se prépare à commémorer la centenaire de sa fondation, je me fais un devoir et me donne la joie d'adresser à son Comité de Rédaction et à son vaillant Directeur mes plus chaudes félicitations.

Le monde médical tout entier participera à ce jubilé et sera de cœur avec les confrères anglais réunis pour fêter cet anniversaire, et inaugurer en même temps le deuxième centenaire de leur grand périodique professionnel. Car il n'est pas douteux que le robuste journal qui honore depuis vingt lustres la science médicale britannique, continuera à marcher allègrement dans la voie glorieux qu'il a suivie pour le plus grand bien de la corporation.

Tous ceux qui lisent THE LANCET seront d'accord, je pense, pour reconnaître qu'elle a été le plus valeureux champion des revendications professionelles en Angleterre, au même temps qu'elle apportait à la diffusion des travaux scientifiques de ses compatriotes l'appui de ses constants efforts et la puissance de sa vaste publicité. Nul organe plus que THE LANCET n'a lutté courageusement pour assurer le relèvement et l'organisation de la profession médicale ; je ne crois pas me tromper en estimant que le General Medical Council, frère aîné de notre Fédération Médicale Belge, est le fruit de campagnes où votre journal fut toujours aux avant-postes. Et ce ne sera pas son moindre titre de gloire, par exemple, que d'avoir contribué d'une manière prépondérante à l'équité des nominations hospitalières qui jadis étaient trop souvent, en Angleterre comme dans d'autres pays, livrés au hasard ou à l'arbitraire.

Je n'ai pas la fatuité, en vous écrivant ces quelques mots, de vouloir définir le rôle important que les collaborateurs de THE LANCET ont rempli au cours des cent premières années de son existence. Mais je suis certain que dans un pays qui doit beaucoup de sa grandeur à l'énergie individuelle et à l'initiative privée de ses citoyens, on appréciera hautement, comme on le fait partout l'influence capitale de vos rédactions dans l'institution si noble et si généreuse des National Hospital Funds. Que de malheureux doivent à l'inspiration et constant dévoûment de votre journal d'avoir trouvé dans les établissements hospitaliers soutenus par le public anglais, la sécurité d'un home comfortable et le secours de soins éclairés et minutieux qu'ils n'eussent pu recevoir chez eux !

"Travail, justice, générosité" pourrait être votre devise. En Belgique nous n'oublierons jamais que votre vaillant périodique contribua largement à la récolte des fonds réunis en Angleterre pendant la guerre récente en faveur des médecins et pharmaciens belges sinistrés. J'ai eu le bonheur d'aller remercier personellement nos confrères anglais de leur touchante et effective solidarité ; je saisis l'occasion que m'offre cette lettre pour vous redire une fois de plus notre gratitude. Je suis convaincu de traduire les sentiments mêlés d'admiration et de reconnaissance du corps médical belge tout entier en félicitant chaleureusement THE LANCET à propos de son jubilé.

Veuillez faire part de nos congratulations à vos collègues de la Rédaction, et recevoir pour vous et pour eux l'expression de ma sympathie personelle at de ma fervents considération.

V. PÉCHÈRE,
Professor of Medicine in the University of Brussels.
Bruxelles, le 15 Septembre, 1923.

May I be allowed to congratulate the proprietors of your illustrious journal and yourself, as its present editor, on the Centenary of its foundation which is about to be celebrated? THE LANCET may well be proud of its century of effort in the quest of human advancement. For fully half that time I have read its numbers and so have felt myself kept in constant touch with all that is best in medicine and with the most sane views on all the phases of its progress. Whilst faithfully chronicling the changes and discoveries in medicine and the allied sciences, THE LANCET in its editorial columns has not failed "to point a moral or adorn a tale," and so to present a fascinating and an inspiring review of the history of the healing art in its continuous making. That another century of high achievement await you is the sincere hope of

R. DOUGLAS POWELL,
Late President, Royal College of Physicians of London.

The surgical history of the eighteenth and the first half of the nineteenth century is full of interest, for it marks the rise of scientific surgery and the beginning of systematised teaching of the subject. John Hunter was the originator of scientific surgery in England, and he owed little or nothing to foreign sources. He was the founder of a great school whose influence was felt with increasing force by each generation of surgeons until the work of Lister explained much that Hunter had foreseen but was unable to explain. The desire for systematic teaching appears to have risen from the lower ranks of the profession. The leaven had been working for some time, as is shown by the "dispensary battles" of a previous generation, but the desire died down until the lean years at the beginning of the last century, resulting from the long wars in which the country had been engaged, led many members of the medical profession to desire payment for advice rather than for medicine. Before they could charge for advice, however, it was necessary that they should have been better taught than by the older methods which had remained unchanged for centuries—a rough apprenticeship followed by the practice of pure empiricism without any previous test of knowledge. The outcome of the increased desire for education was the passing of the Apothecary's Act of 1815. The Act required that a person who was going to practise medicine must be licensed, and before he could be licensed must show that he had received a fair general education and had acquired at least the rudiments of professional knowledge. Many schools arose at once in London to provide the requisite teaching, some attached to the large hospitals of the metropolis, others private schools conducted by men of great ability who for one reason or another had failed to secure a position on the staff of the hospital where they had themselves been pupils. The rivalry between the hospital and private schools was bitter and unscrupulous. The younger men at the private schools were in many cases the better teachers, and as their entire livelihood depended on the success of their teaching they gave of their best; the teachers at the hospital schools were better organised and held influential positions at the licensing boards, where they were often examiners. There is no doubt that they used their powers tyrannically; the private schools were suppressed or compelled to throw in their lot with the hospital teachers, and there only remained a miserable class of "grinders," who lingered on until quite recent times. During the greater part of this period there was no professional journalism as distinct from a medical press dealing entirely with medicine in its scientific aspect, and polemics were carried out by flysheets, open letters, and pamphlets, as is still the custom at the Universities of Oxford and Cambridge. The appearance of THE LANCET altered the whole aspect of things, and threw light on many dark corners of contemporary surgical practice.

For centuries it had been the custom for surgeons attached to the hospitals to bring their apprentices with them to see how patients should be treated. At first they merely received the ordinary apprenticeship fee like other masters of city craft, but in process of time it was found that apprentices to hospital surgeons acquired greater privileges than were given those whose masters did not hold such a post. The hospital surgeons were not slow to take advantage of this, and they demanded much larger apprenticeship fees than was usual; or else, as was natural, they took intelligent members of their own family into their service. The result was not difficult to foresee. The pupil succeeded his master at the hospital, and in process of time he did so occasionally to the exclusion of better men. The early numbers of THE LANCET were devoted to the destruction of this system. Violent attacks were made upon individuals, for it was thought that deeply-rooted evils required rough measures to expose and deal with them. But the methods adopted cannot be judged by the standards of to-day. People in the first half of the nineteenth century were much more outspoken than they are at present, men hated each other with undisguised hatred, habits were coarse, feeding was gross, and tempers were short, so that what now appears to us brutal was not then considered outrageous. Principles were attacked as well as individuals, and in the end THE LANCET was found to have done the profession good and to have raised the general tone by its rough attacks. The amelioration of manners led gradually to a softening of tone in THE LANCET, but did not in any way lead to a deviation from the path of reform which had been marked out for it by its Founder.

D'ARCY POWER,
Consulting Surgeon, St. Bartholomew's Hospital.

A hundred years of public-spirited service to the profession finds THE LANCET still with undulled point, bright and trenchant as ever! Its keenness, as that of its synonym, has often boldly and wisely brought relief from mischief threatening the general health, and given issue to much laudable matter. On occasion it has, most usefully, resigned itself to pricking a bubble. On it the medical man relies, and with him it goes Britain's world over, a means to his skill, an aid to his science, a mirror and epitome of his experience. Able and beneficent the hands that have directed it so successfully; in all earnestness, even thus may it continue, indispensable, untarnished, and fine of temper as in the past and present, so through the century to come.

C. S. SHERRINGTON,
President of the Royal Society.

On the eve of the completion of its Centenary I should like to offer through you my congratulations on the high reputation which THE LANCET has won, and my best wishes for its continued influence and authority. From inside knowledge and from independent observation I am confident that the Editors, all of whom I have known personally, except the first, have throughout striven to promote the welfare, advancement, and prestige of the medical profession, and the improvement and safety of the public health.

JOHN TWEEDY,
Late President, Royal College of Surgeons of England.

The real significance of a centenary lies in this: that only that which is superlatively well done—and I may add done by idealists—can last a hundred years. And so when the centenary comes, it is an invitation to remind ourselves that we are debtors, to think for an instant of those to whom we are indebted, and to bear in mind those words of kindliest satire which tell us that those who do good by stealth (in editors' rooms and elsewhere) are delighted to be afterwards found out. Others who are less absorbed in their individual task, and therefore more constant readers, will more fitly praise THE LANCET as an organ of scientific medical instruction. They will call THE LANCET worthy to be loved because it has kept generations of readers in closest touch with the advances of medicine; because only the best work has been placed before them and the inferior has been excluded from its columns. And they will commend it because the editorial comment has continuously distinguished between what is ephemeral and makes a bid for notice and what is solid and of lasting value; and because it has always extended a welcome to the future and decently buried the past.

I leave all this to render thanks for the unforgettable services THE LANCET has rendered to its scientific contributors. My personal indebtedness to it is of the very heaviest. Let me resume it under three headings:—

1. Practically all my research work has found first publication in its columns, and it has never spared itself heavy expense. It has permitted me heavy proof corrections which I have never yet learned how to avoid. And, above all, when the cause of antityphoid inoculation was, after the Boer War, making very heavy weather it published for me a special supplement, comprising 24 statistical records, with much comment and critical matter.

2. There has been given to all my papers very careful and valuable proof-reading. Every fellow-contributor to THE LANCET knows what the quality of that proof-reading is.

3. THE LANCET is, when a question of medical science is at stake, not only lavish, but it has on such occasions the quality of moral courage—that quality without which every other virtue can be written off as inoperative.

ALMROTH E. WRIGHT,
Principal, Institute of Pathology, St. Mary's Hospital.

Medical News.

UNIVERSITY OF CAMBRIDGE.—The University Grants Committee have decided to make an additional annual grant to the University of £30,000 to provide for pensions and stipends, for the maintenance of the library, and the extension of extra-mural work and on the women's colleges. For the last purpose £4000 per annum will be definitely allocated for the next ten years.

UNIVERSITY OF LONDON.—The Semon Lecture for the year 1922–23, entitled the Advancement of Laryngology, will be given at the House of the Royal Society of Medicine, 1, Wimpole-street, W. 1, by Dr. Arthur Logan Turner, on Nov. 1st, at 5 P.M. The chair will be taken by Mr. Charles A. Parker. Admission is free, without ticket.

University College.—Among the public lectures arranged for the session 1923–24 are the following: On Oct. 10th, at 5 P.M., a public lecture by Mr. Morris Ginsberg will be given on the Sociological Work of the late Dr. W. H. R. Rivers, and at 7 P.M. Mr. A. H. Barker will discuss the Heating Equipment of a Small House. On Oct. 15th, at 5 P.M., Miss I. C. Ward will lecture on the Application of Phonetics to the Curing of Speech Defects. On Oct. 16th, at 5.30 P.M., Prof. A. V. Hill, F.R.S., will give a public inaugural lecture on the Present Tendencies and Future Compass of Physiological Science, Prof. E. H. Starling, F.R.S., presiding. On Oct. 23rd, at 5.30 P.M., Mr. Percy Flemming will speak on the Care of School-Children's Eyesight. On Oct. 26th, at 5.15 P.M., Mr. B. Seebohm Rowntree will speak on Factory Life as it is and as it might be, and on Oct. 29th, at 5 P.M., Miss Iza Thompson will discuss the Teaching of Speech to Deaf Children. Prof. G. Dawes Hicks will give six public lectures on the Fundamental Concepts of Natural Science on Nov. 2nd, 9th, 16th, 23rd, 30th, and Dec. 7th. On Nov. 9th, at 5.15 P.M., Prof. J. C. Drummond will give an address on Vitamins. On Nov. 29th, at 5.30 P.M., Sir William J. Collins will give a public lecture on the Life and Doctrine of Sir Edwin Chadwick, and on Dec. 7th, at 5.15 P.M., Prof. Karl Pearson, F.R.S., will give a public lecture on Eugenics. Admission to these lectures is by ticket to be obtained from the Publications Secretary, University College, Gower-street, London, W.C. 1.

King's College and King's College for Women.—Nine lectures on the Biological Foundations of Society will be given by Prof. Arthur Dendy, F.R.S., on Wednesdays, at 5.30 P.M., beginning on Oct. 17th.

Bedford College for Women.—A public lecture on the Treatment of Memory-Images in Modern Psychology will be given by Miss B. Edgell on Oct. 10th, at 12 noon, and on the Quantum Theory and Electromagnetic Phenomena, by Prof. W. Wilson, F.R.S., at a time to be arranged.

UNIVERSITY OF GLASGOW.—Prof. John Ronald Currie, M.A. Edin., M.A. Oxon., M.D. Glasg., D.P.H. Birm., M.R.C.P.E., who has been elected Henry Mechan Professor of Public Health in the University of Glasgow, was appointed professor of preventive medicine in Queen's University, Kingston, Canada, in 1922. His early appointments included those of house physician and house surgeon at the Glasgow Royal Infirmary and resident medical officer at the Glasgow Maternity Hospital. He then became senior assistant physician to the Belvidere Fever Hospital, Glasgow, and later physician in charge of the City of Glasgow Small-pox Hospital. From 1907 to 1912 he acted successively as acting medical officer of health to the counties of Stirling and Dumbarton, assistant medical investigator to the Royal Commission on Poor-Laws, medical officer of health and principal school medical officer to the city of Chester, and medical officer of health and principal school medical officer to the counties of Fife and Kinross; in 1912 he was appointed medical officer to the Scottish Insurance Commission. During the war he acted as specialist sanitary officer in various districts, and from 1919 to 1922 was a medical officer to the Scottish Board of Health.

GUILD OF ST. LUKE.—The annual service will be held at St. Paul's Cathedral on St. Luke's Day, Oct. 18th, at 7 P.M. Seats will be reserved for medical practitioners and students, all of whom are invited to attend, whether they are members of the Guild or not. The Guild of St. Luke, which was founded in 1864, has for its object the mutual encouragement and support of its members in leading a Christian life. Membership of the Guild is open to students and practitioners of medicine who are communicants of the Church of England, the clergy of which are eligible for election as Clerical Associates. Tickets for the service and further particulars concerning the Guild may be obtained on application to the Guild Secretary, the Rev. H. Kirkland-Whittaker, M.A., M.D., Chaplain's House, Banstead Downs, Sutton, Surrey, or to the Secretary of the Women's Ward, Dr. Isabel Pulteney, 2, Bryanston-place, London, W. 1.

MEDICAL SOCIETY OF LONDON.—The Fothergillian medal and prize have been awarded to Sir Arthur Keith and will be presented to him at the general meeting of the Society on Monday, Oct. 8th, at 8 P.M.

ST. ANDREWS INSTITUTE.—The sum of £5000 has been received as a first instalment of a fund being raised in Perthshire for the support of the Institute founded by Sir James Mackenzie, a Perthshire man.

POST-GRADUATE COURSE AT MANCHESTER.—A free course of eight lectures will be given by the surgical staffs of the Salford Royal Hospital and Ancoats Hospital on Surgical Tuberculosis, on Thursdays at 4.30 P.M., commencing on Oct. 18th.

VICTOR HORSLEY MEMORIAL LECTURE.—The first Victor Horsley Memorial Lecture will be delivered by Sir Edward Sharpey Schäfer in the Barnes Hall of the Royal Society of Medicine, 1, Wimpole-street, on Thursday, Oct. 25th, at 5 P.M., on the Relations Between Surgery and Physiology. All members of the medical profession will be admitted on presentation of their cards.

THE gold medal founded by Sir Gilbert Blane has been awarded by the Director-General of the Medical Department of the Navy and the Presidents of the Royal College of Physicians of London and the Royal College of Surgeons of England to Surgeon-Lieutenant Commander Julian L. Priston, M.B., M.R.C.P., D.P.H., R.N.

SCHOOL MEDICAL SERVICE AT YARMOUTH.—The Board of Education have expressed their approval of the school medical service for the current year, but have given the authority to understand that the present arrangements for treatment of defects are in their opinion inadequate. Accordingly, Dr. A. N. Stevens has outlined a scheme for treatment of minor ailments, visual defects, and dental treatment. Cleanliness surveys by a nurse are also contemplated.

LONDON SCHOOL OF DERMATOLOGY.—In order to further the study and teaching of dermatology in London, a scheme has been completed whereby teaching will be conducted at St. John's Hospital for Diseases of the Skin by the honorary medical staff of the hospital, together with the physician in charge of the dermatological departments of the 12 London teaching hospitals. Full details will be published later, but in the meantime the announcement in our advertisement columns of lectures to be given on Tuesdays and Thursdays at 5 P.M. during the winter session may be consulted.

ECONOMY IN THE ISLE OF ELY.—A decision to dispense with the services of a second medical officer under the Isle of Ely County Council was followed by a request from the county medical officer, Dr. J. P. Walker, for a testimonial relating to the work he has already done for the Council with a view to applying for another appointment. He pointed out that the Council have admitted that the work cannot be performed satisfactorily by one medical officer, and that he feels that, although his work under the authority has so far been carried on under harmonious conditions, such conditions are not likely to prevail when the proposed extra duties are unsatisfactorily performed owing to the inability of one man to cope with them. A deputation to the Board of Education and the Ministry of Health have already been told by these departments that in their opinion the work cannot be satisfactorily performed by one officer.

SUNDERLAND ROYAL INFIRMARY.—On Sept. 26th the new operating theatre block, built and equipped in memory of the late Mr. J. Y. Short, at a cost of £7000, was opened by his widow and his son, Mr. T. Short. Dr. Wm. Robinson, chairman of the medical board, described the new building and said that the site had been carefully selected so that the block would not interfere with the future extension of the wards of the Infirmary, which was much needed because of the great length of the waiting list. The block consists of a suite of 11 rooms opening off a central corridor—namely, (1) a dark room for examination of the eye, ear, throat and nose, cystoscopy, &c., in which mastoid and similar operations can be done; (2) a recovery room with two beds; (3) surgeons' preparation room with six lockers, a long and a shower bath, wash-basin, and w.c.; (4) an anæsthetising room; (5) and (6) two large theatres, one side of each and part of the sloping roof are of glass; (7) an instrument and surgeons' final preparation room; (8) a sterilising room; (9) sisters' room; (10) a housemaids' room; and (11) store room. Dr. Robinson showed that these two additional theatres would admit of a throat and ear department being established, and also of increase of the size of the eight old wards which was necessary in the future.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Oct. 8th.

WAR: at 5 P.M.
Presidential Address:
Air Commodore D. Munro: The Possible Uses of the Aeroplane in the Medical Services in Future Warfare.

Tuesday, Oct. 9th.

THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.
Discussion:
On the Use of Insulin in General Practice, to be opened by Prof. Hugh Maclean, followed by Dr. George Graham, Prof. J. J. R. Macleod (Toronto), and others.

Thursday, Oct. 11th.

NEUROLOGY: at 8.30 P.M.
Presidential Address:
Dr. James Collier: The Pathogenesis of Cerebral Diplegia.

Friday, Oct. 12th.

CLINICAL: at 5.30 P.M. (Cases at 5 P.M.)
Cases will be shown.
OPHTHALMOLOGY: at 8.30 P.M. (Cases at 8 P.M.)
Cases will be shown.
Paper:
Mr. T. Harrison Butler: Muscle Recession in Strabismus.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Oct. 8th.—8 P.M., Annual General Meeting. The Fothergillian Medal and Prize will be presented to Prof. Sir Arthur Keith, F.R.S., at this meeting. 8.30 P.M., Ordinary Meeting. President's Address On Some Changes in Obstetric Practice since the Foundation of the Medical Society of London, by Dr. Herbert Spencer.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: OCTOBER–NOVEMBER, 1923.

CLINICAL LECTURES AND DEMONSTRATIONS.

MONDAY, Oct. 8th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Myasthenia Gravis: Dr. James Taylor.

TUESDAY, Oct. 9th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Parasyphilitic Affections and their Treatment: Dr. Risien Russell.

THURSDAY, Oct. 11th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Hemiplegia: Dr. Walshe.

FRIDAY, Oct. 12th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Hæmatomyelia: Dr. Collier.

COURSE OF LECTURES AND DEMONSTRATIONS ON NEURO-PATHOLOGY.

MONDAY, Oct. 8th.—12 noon, Cerebro-spinal Fluid, Anatomy, and Physiology: Dr. J. Godwin Greenfield.

A COURSE of LECTURES on the ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM will be arranged if there are sufficient entries for it.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

The fee for the Course, including Pathology, is £5 5*s*. The fee for the Anatomy and Physiology Lectures will be £3 3*s*., but this Course will only be given if six or more entries are received. If taken in conjunction with the Clinical and Pathological Courses, an inclusive fee of £7 7*s*. will be charged. Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the office on entering for the Course.

C. M. HINDS HOWELL, Dean of Medical School.

LIVERPOOL UNIVERSITY CLINICAL SCHOOL.

(At 3.30 P.M. each day.)

MONDAY, Oct. 8th.—(Children's Hospital.) Mr. Dun: Surgical Treatment of Tubercular Glands.

TUESDAY.—(Southern Hospital.) Dr. Macalister: Ateleiosis and Stunted Growth.

WEDNESDAY.—(Northern Hospital.) Mr. Monsarrat: Cholecystitis.

THURSDAY.—(Stanley Hospital.) Mr. Evans: The Acute Abdomen in the Child and Adult.

FRIDAY.—(Royal Infirmary.) Mr. Thelwall Thomas: Surgical Cases.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, Oct. 8th.—10 A.M., Mr. Maingot: Surgical Pathology. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.

TUESDAY.—10 A.M., Mr. Steadman: Dental Department. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Dr. Pritchard: Medical Wards.

WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 12.15 P.M., Dr. Burnford: Medical Pathology. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.

FRIDAY.—11 A.M., Dr. McDougal: Electrical Department. 12 noon, Dr. Endean: Venereal Diseases. 2 P.M., Mr. Sinclair: Surgical Out-patients.

SATURDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Dr. Burnford: Medical Wards. 10 A.M., Dr. Banks-Davis: Operations on the Throat, Nose and Ear.

Daily, 10 A.M. to 6 P.M., Saturday, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, Oct. 9th.—4.15 P.M., Mr. H. H. Rayner: Difficulties and Pitfalls in the Diagnosis of Acute Abdominal Diseases.

FRIDAY.—4.15 P.M., Dr. F. Craven Moore: Modern Conception and Investigation of Dyspepsia.

Appointments.

CURRIE, J. R., Professor of Preventive Medicine at Queen's University, Kingston, Canada, has been appointed to the chair of Public Health, Glasgow University.

PATRICK, A., M.B., Ch.B. Glasg., F.R.F.P.S.G., Professor of Medicine at St. Andrews University.

TURNER, A. A., M.B., Ch.B. Aberd., D.P.H., Deputy Medical Officer of Health and School Medical Officer, Croydon.

Manchester Royal Infirmary: **SHAW**, R. C., M.R.C.S., L.R.C.P., Second Surgical Registrar; **HICKSON**, S. K., M.B., Ch.B. Manch., M.R.C.P. Lond., Cardiological Registrar; **MITCHELL** W., M.B., Ch.B. Manch., and **LOWE**, G., M.B., Ch.B. Manch., Clinical Assistants; **DUTHIE**, O. M., M.B., Ch.B. Manch., Resident Medical Officer, Barnes Convalescent Hospital, Cheadle.

Certifying Surgeons under the Factory and Workshop Acts: **CROMIE**, G., M.B., Ch.B. Edin. (Bridgwater); **DOHERTY**, W. I., M.B., Ch.B. Leeds (Maidenhead).

Vacancies.

For further information refer to the advertisement columns.

Ashton-under-Lyne Union.—Med. Supt., &c. £450.
Birmingham General Dispensary.—R.M.O. £450.
Bristol Royal Infirmary.—Hon. Dental Surgeon.
Bury Infirmary.—Jun. H.S. £150.
Cardiff Royal Infirmary.—Hon. Dent. S.'s. Also Hon. Asst. S.
Croydon Borough Sanatorium, North Cheam.—Res. Med. Supt. £750.
Derby County Mental Hospital, Mickleover.—Asst. M.O. £350.
Derbyshire Royal Infirmary, Derby.—Two H.S.'s., H.P., &c. Each £200.
Egyptian Government School of Medicine.—Lecturer in Experimental Physiology. L.E.540 a year.
Gloucestershire Royal Infirmary.—Hon. Anæsth. Two Hon. Dental Surgeons.
Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. Also Res. M.O. £500.
Hospital for Epilepsy and Paralysis, Maida Vale, W.—R.M.O. and H.P. £150 and £100.
Hospital for Sick Children, Great Ormond-street. W.C.—H.P. and Asst. Cas. O. £50. H.S. £50.
Hull City Asylum.—Jun. Asst. M.O. £300.
Leeds Public Dispensary.—Sen. Res. M.O. £200. Jun. Res. M.O. £150.
London County Mental Hospital Service.—Seventh Asst. M.O. £432.
London Lock Hospital, 91, Dean-street, W.—H.S. £200.
Lowestoft, St. Luke's Hospital.—Jun. Asst. M.O. £500.
Manchester Hospital for Consumption and Diseases of the Throat.—Hon. Asst. Phys.
Manchester, Victoria Memorial Jewish Hospital.—Res. M.O. £150.
Mount Vernon Hospital for Diseases of the Chest, Northwood, Middlesex.—Asst. Phys.
Nottingham Cripples' Guild.—Hon. Orthopædic S.
Oswestry, Shropshire Orthopædic Hospital.—Res. Surg. O. £500. Two H.S.'s. £250.
Paddington Green Children's Hospital, W.—H.P. and H.S. Each £150.
Royal Eye Hospital, St. George's Circus, Southwark, S.E.—Hon. Asst. S. Also Jun. H.S. £75.
Salford Royal Hospital.—Hon. Dent. S.
St. Mary's Hospital, Paddington, W.—Med. Supt. £350.
Staffordshire General Infirmary, Stafford.—H.S. £200.
Talgarth, Breconshire, Mid Wales Counties Mental Hospital.—Asst. M.O. £350.

The Secretary of State for the Home Department gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act, 1906, for County Court Circuit No. 32 (attached more particularly to the Attleborough, Aylsham, Downham Market, East Dereham, Fakenham, Holt, King's Lynn, North Walsham, Norwich, Swaffham, Thetford, and Wymondham County Courts). Applications are invited preferably from medical practitioners resident in West Norfolk, and should be addressed to the Private Secretary, Home Office, so as to reach him not later than Oct. 20th.

Births, Marriages, and Deaths.

BIRTHS.

WRIGHT.—On Sept. 22nd, at Wingfield-road, Trowbridge, the wife of Dr. Roger Wright, of a daughter.

MARRIAGES.

DAVIES—SLY.—On Sept. 26th, at the Parish Church, Wrexham, John E. H. Davies, D.S.O., M.R.C.S., of Plas Darland, Wrexham, to Nona, daughter of Dr. and Mrs. Sly, Sydney, Australia.

DUKE—HUNT.—On Sept. 25th, at St. Paul's, Camden-square, Harold Denny Duke, M.R.C.S., L.R.C.P., to Dorothy Ann Hunt, second daughter of the late Joseph Hunt, J.P., and of Mrs. Hunt, of the Pynes, Canterbury.

FRASER—BAILEY.—On Sept 26th, at the West Parish Church, Helensburgh, Matthew William Fraser, West African Medical Staff, to Grace Eileen Bailey, only daughter of the late Reginald Bailey, Limpsfield, Surrey.

OAKDEN—MOSTYN.—On Sept. 27th, at St. John's Church, Torquay, George Marshall Oakden, L.R.C.P., M.R.C.S., L.D.S., to Enid May, third daughter of Tom Mostyn and Mrs. Mostyn, Crookham, Torquay.

DEATHS.

MOWAT.—On August 21st, at Kuala Lumpur, Harold Mowat, M.D., Ch.B., Radiologist to the Government of the Malay States, late Captain, R.A.M.C., and Surgeon, R.N., aged 40 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

THE next general meeting of the Society for Constructive Birth Control and Racial Progress will be held on Thursday, Oct. 18th, at 8 P.M., at Essex Hall, Strand, when a presidential address will be delivered by Dr. Marie Stopes on Medical Contradictions and Mistakes in Evidence in Her Recent Case. Those interested in the Society should apply for information to the Hon. Sec., C.B.C., 7, John-street, Adelphi, W.C. 2.

Notes, Comments, and Abstracts.

SOME BALKAN REMEDIES FOR DISEASE.

AN attack of sciatica during a visit to Albania furnished its victim, Miss M. E. Durham, with some entertaining reminiscences of the herbal and other remedies, including spells and magic, of local fame, which she records in the September number of *Man*. The wish of the people to kill a pelican and rub her leg with its fat because pelicans always get their feet wet and never have rheumatism, was discouraged by the doctor attached to the Austrian hospital. Other prescriptions suggested were: (1) to beat the limb with stinging nettles; (2) to rub it with roasted onions boiled in oil (this was tried and, in the form of gentle massage, gave some relief); (3) to slaughter a sheep and wrap the patient in the raw hide because the sheep eats all kinds of herbs, and their virtue will soak into the patient. The doctor's protest against this last remedy succeeded in view of his vivid description of a visit to a patient to whose skin a split black cat had been applied some ten days before. Miss Durham found among the Christians a great belief in the efficacy of Moslem spells, while Moslems resort to Christian rites for a cure. Her guide had himself been cured of rheumatism by a magician who had waved certain herbs over a fire, muttering spells, and had then placed the bunch of herbs on the patient's head saying: "Pain, pain, leave this man and go to the top of a high mountain, where there is neither man nor beast, and stay there." Another equally efficacious method was to cut some hair from the crown of the head of the patient, and some from each armpit, and burn it in a brazier, saying: "May the pain disappear as does this hair." The pain, according to Albanian peasants, obeys and never comes back. A cure for jaundice was to find a red rose and to tie a piece of yellow wool round it, tying a piece of red wool round the child. The magician says: "Yellow, yellow, go out of the child and into the rose. Red, red, go into the child." In a few days' time the rose withers and turns yellow, and the child resumes its natural colour! An even better remedy, she was informed, is to catch a small fish and put it in a bucket of water. The patient must fix his eyes on it as it swims round and round; after a time the disease goes into the fish and it dies, and the patient recovers. A certain cure for epilepsy difficult to obtain involves the detection of a snake in the act of swallowing a frog. A black handkerchief thrown over the snake frightens it and it disgorges the frog. If the handkerchief is kept carefully, and thrown over someone in a fit, the disease similarly will be disgorged.

In parts of Montenegro there were Austrian and Russian doctors practising, and home-made treatment was being gradually superseded. In the Tsrmnitza valley hernia is cured by old women in this wise, the fee for each operation being 2*d*. and a gift of a cheese or some eggs. The name and address of the patient has to be divulged but his presence is not necessary. Some freshly drawn water is put into a metal, long-necked jug (ibrik) and set to boil on the fire, with the words: "Water, I call on you three times from Heaven to earth—let the bowel of Mr. 'X' return to its place." When the water boils it is poured at once into a metal shallow basin and the ibrik inverted with its mouth in the water. As the ibrik cools a certain amount of the water rises up into the neck—the more the luckier—and so should Mr. "X's" bowel return to its place. The charm is repeated daily till relief is experienced, and such faith does it inspire that Montenegrins afflicted abroad write home to have the charm performed.

THE RISKS OF WIRELESS APPARATUS.

IN a recent report of the "Radio Hazards" Committee of the National Safety Council, Chicago, Ill., the assertion is made that carelessness and ignorance are responsible for nearly all accidents that occur during the handling of wireless apparatus. The quantity of such accidents is stated to be small, considering the great numbers of people who now own, erect, and use wireless sets, but for the guidance of amateurs the committee gives advice, of which the following is the substance:—

"The handling of antenna wires after they have become charged by falling on or touching high voltage power and light wires (or by those wires falling on the aerials) has resulted in severe shock and death. The collapse of antenna masts due to improper or insufficient guying has led to such cases as well as to serious falls. An outdoor aerial is not necessary for efficient reception of radio messages. The use of an indoor aerial eliminates contact with outside power and light wires and the hazard of climbing to unfamiliar places. A lightning arrester, while not absolutely necessary, should be installed. Storage batteries have caused several accidents, due to the fact that after charging expelled oxygen and hydrogen gases (an explosive mixture) have come in contact with an open flame or have been ignited by crossed wires. Spilling or leaking of electrolyte (usually sulphuric acid) has ruined interior furniture and caused severe body burns.

There is ample current capacity in dry cell batteries to produce a fatal shock, but ordinarily the voltage is not sufficient to force this fatal shock through the body. A good general rule for avoiding shock is to use one hand only and be sure the body is nowhere grounded. The sending station should preferably be located in a building of substantial construction, and should derive the current necessary for operation from a source other than the supply to the building for other purposes. The lead-in wire should be kept 5 inches away from all parts of the building. The same air space should be provided for all ground wires. Splices and joints in the antenna span and lead-in wires, unless made with approved clamps or splicing devices, should be soldered. All antennas and lead-in wires should be of copper or approved clad steel not smaller than No. 14 B. and S. gauge. The lead-in wires should enter the building only through non-combustible, non-absorptive insulating bushings."

In the United States, "generally speaking, fire insurance companies will not be affected adversely by the installation of radio receiving sets even with outdoor antennas. It is suggested, however, that those who wish to make certain of this point, call up their insurance broker, who will either give verbal consent to the addition or will issue a radio permit endorsement for the fire insurance policy without charge or change in rate."

ASSOCIATION OF CERTIFICATED BLIND MASSEURS.

SPEAKING recently at the general meeting of the Association of Certificated Blind Masseurs, Sir Robert Jones, President of the Association, quoted figures to show the progress made by the Association during the year 1922–23. At the termination of its fourth financial year the Association numbered 160 members, of whom 81 were ex-soldiers 37 civilians, and 42 masseuses. The general public and even some of the medical profession, he said, were badly in need of information about massage and the blind masseur. There was a popular idea that the Association was of the nature of a transient war charity, and out of this misconception had arisen the belief that, however excellent a blind masseur might be, and however patriotic it might be to employ him, he could not, of course, equal the skill of a masseur with sight. That the blind were specially suited to become masseurs was now a commonplace amongst all who had supervised their work. They acquired in certain sympathetic directions a deftness and delicacy of touch not often found in the ordinary masseur—they worked by insight and with that compensation of nature, by which where one faculty was weakened, another was made strong. It was imperative that the Association should dispel the view that the blind masseur could not compete in the open market, and that the idea of him, both as a post-war problem and as an amiable charity, should be demolished. The official organ of the Association is published monthly in embossed type, and contains lectures and articles on massage and kindred subjects by eminent medical men. Through the generous help of the National Institute for the Blind the journal is embossed and despatched free of charge to all registered members of the Association.

SMITH'S PHYSICIANS' AND SURGEONS' VISITING LISTS.

A VISITING list in the form of a pocket-book is almost an essential for the busy practitioner. Smith's Physicians' and Surgeons' Visiting List (published by Messrs. Hazell Watson and Viney, 52, Long Acre, London, W.C. 2) has now appeared for 78 years—a measure of its popularity. Bound in cloth boards or in leather, with tuck pocket and pencil, these books measure 6¼ by 3½ in., and consist mainly of ruled pages for keeping a record of visits, obstetric and vaccination engagements, patients' and nurses' addresses, and so forth. A section devoted to things lent is a modern and useful feature for any diary. There is a preface of some 32 pages of ready information for the doctor, such as the dosage tables of the British Pharmacopœia, tables for calculating the period of uterine gestation, suggested professional charges, lists of poisons and antidotes, &c. The inclusion of a short summary of requirements under the Registration and Notification of Births Acts and of a form for making a will indicates the comprehensiveness of the book. Prices vary from 6*s*. 6*d*. to 12*s*. 6*d*. according to binding and ruling, and books can be obtained for keeping records of from 25 to 200 patients, the largest size being rather bulky for pocket use.

"CHEMISTS TO A NATION"

WIDESPREAD ACTIVITIES OF "BOOTS THE CHEMISTS."

A GREAT MANUFACTURING, DISTRIBUTING AND RETAILING CONCERN

BY HERBERT HILL.

HACKNEYED as it may be, the old saw "Great oaks from little acorns grow" has nevertheless a triteness about it and a ring so typically British, that it seems particularly appropriate when used to epitomise the birth and phenomenal growth of that great organisation known practically throughout the length and breadth of the land as "Boots The Chemists."

When, in the early seventies, half a century ago, the young lad, Jesse Boot, took over his dead father's little shop for the sale of herbs, situate in the unpretentious thoroughfare of Goose Gate, in the centre of the City of Nottingham, the acorn was planted which, in due course, was to take root and grow to be one of the largest and most powerful retail shop-owning concerns in the world.

A Many-sided Organisation.

But, although it is as owners of attractive shops wherein are retailed drugs and medicines, and toilet and personal requisites, that the firm of Boots the Chemists is so widely known and patronised by the public, the concern is, as a matter of fact, much more than a company of shopkeepers. The widespread network of retail chemists' shops has behind it a vigorous many-sided organisation at first glance bewildering in its complexity, but which, upon a closer scrutiny, very quickly demonstrates a truly remarkable efficiency.

Before proceeding in any way to enlarge upon those activities of the Boots organisation which do not directly evidence themselves to the millions of people using its shops, it may be as well to state that the undertaking comprises a group of six joint stock companies. They are :—

Boots Pure Drug Company, Ltd.
Boots Cash Chemists (Eastern), Ltd.
Boots Cash Chemists (Lancashire), Ltd.
Boots Cash Chemists (Northern), Ltd.
Boots Cash Chemists (Southern), Ltd.
Boots Cash Chemists (Western), Ltd.

Five Millions of Capital—40,000 Shareholders.

The total capitalisation of these six companies is £5,000,000, and the shares are held by no less than 40,000 shareholders domiciled all over the country.

The original, and still the parent concern, is Boots Pure Drug Company, Ltd., whose very important function is the buying of all raw material and its manufacture and distribution to the hundreds of branches owned by the five subsidiary retailing companies—those distinctive shops which are so familiar a feature of the principal shopping thoroughfares of nearly every town or city of any size in the Kingdom.

The Head Offices of all the six companies are at Nottingham, within a stone's throw, so to speak, of the site upon which stood the original little shop which was to be the forerunner of the present-day Boots organisation, and the whole of the administrative work of the business is directed from that centre.

More than 900 people are engaged on the administrative side, and a vast amount of detail work is performed by them. Exhaustive digests, dissections, and costings are undertaken, and thus a very close watch is kept on all such matters as manufacturing costs of production, stocks, records, branch finance, and so on.

Activities and Assets.

That such a large clerical staff is necessary will be easily understood once an appreciation of the ramifications and magnitude of the organisation behind the retail distribution is gained. Some of its activities and assets may be briefly set out as follows :—

First of all, in addition to running nearly 700 thoroughly up-to-date chemists' shops, the Boots concern manufactures on a huge scale all kinds of medicinal and pharmaceutical preparations, for which purpose it possesses one of the most extensive and up-to-date plants in the world. No less than 35 per cent. of the great volume of pharmaceutical products sold over the counters of the Boots shops are manufactured by the organisation itself.

It has extensive research and analytical laboratories under the most highly skilled technicians. And, supplementing the important part these laboratories play in connection with the demands of the organisation of which they form so essential a unit (some 70,000 analyses were undertaken last year), research work which has proved of great national value is carried on.

It owns printing works giving employment to 400 people. These printing works are a model of their kind, and are frequently visited by people from all over the country interested in printing.

It has a plant for the manufacture of extract of malt with cod-liver oil with a capacity of 500 tons per annum.

It operates a soap-works and a perfume distillery, where bath and other fancy soaps and perfumes of all varieties are turned out in large bulk.

It runs a mineral-water factory, and throughout the Midlands in particular Boots mineral waters are widely known.

It is the largest user of Burroughs Adding Machines in the Kingdom.

It runs a bookbindery and a picture-framing factory.

It has a power-house with a consumption of 400 tons of coal a week.

It has a carpentry, joinery and cabinet-making works, turning out showcases, desks, counters, chairs, office furniture and equipment and other internal fittings, as well as designing and making all the shop-fronts required by the subsidiary companies.

It sells well over half a million books in the course of a year, thus dispensing much “ medicine for the soul,” as well as for the body.

BOOTS WORKS, ISLAND STREET, NOTTINGHAM, FOR THE MANUFACTURE OF FINE CHEMICALS.

It has first-aid rooms, an up-to-date surgery and convalescent and holiday homes for the benefit of the employees.

It has a window display department for inculcating the art of window dressing on the approved “ Boots ” lines, and lastly its activities cover the running of a school.

One might go on almost ad infinitum cataloguing the activities and possessions of this versatile concern, but enough has been said to indicate, at least to some extent, the diverse operations embraced by the Boots companies in their endeavour to give to the public a service which shall be the last word in the matter of supplying pure drugs and chemicals, medicinal and toilet preparations and the various side-lines allied thereto.

Nottingham the Headquarters.

All the laboratories, factories, warehouses and workshops enumerated above (and the list is by no means exhaustive) are situated at Nottingham. The floor space of the various buildings approximates 1,055,944 superficial feet, and they stand on some 14¼ acres of land. To make a thorough inspection of them all would call for no mean expenditure of physical effort, but even a quick run through is sufficient to impress one with the wonderful versatility of the concern, and to compel a tribute to the genius which could envisage such an undertaking and to the brains and willing service which carry it ceaselessly forward.

Willing, or perhaps one should rather say, enthusiastic service, seems, indeed, to be the keynote which energises the whole of the staff one meets at Nottingham. Again and again as one wends one’s way from one building to another some particularly ingenious device or clever piece of machinery stands out to catch the eye, but over and above all one senses throughout the entire organisation that spirit of enthusiastic service which goes far to explain the wonderful success of the Boots undertaking.

Up-to-date Working Conditions.

Then, too, one cannot fail to note the spaciousness, cleanliness, and airiness pervading all the many separate buildings. Unquestionably the employees work under the most favourable conditions, and this congenial atmosphere must do much to lessen the possibilities of their work assuming the dull routine of a monotonous task.

And to realise that many of the individual tasks might well become monotonous is but to watch, say, the automatic bottling machines working as rapidly as the attendant girl can work a lever. In many of these mechanical contrivances the output capacity of the machine seems to be limited only by the physical capacity of the human who operates it. It is, therefore, to the advantage of the employer to see that the employee works in the most attractive surroundings. Mechanical genius has made such strides as to eliminate largely the human interest of the workman in his work, and the psychological effects of this can only be countered by ensuring that the environment in which the more or less automatic task is performed is of the best.

Model Shops and Ideal Factories.

This the Boots organisation wholeheartedly attempts to do. Just as the Boots retail shops are models of what such shops should be, so the Boots laboratories, factories and workshops appear to be as near the ideal as it is as yet possible to get. Boots obviously take a pride in their workpeople, in their plant and machinery and in their buildings. Industrial psychology in all its phases is given the most careful study. Nothing seems to be left undone in regard to the comfort and well-being of their employees ; the buildings and premises are constantly undergoing extension and improvement, and the plant and machinery is continually receiving additions and renewals.

Machine Made Pills.

Where there is such an infinite variety of mechanical appliances in use it is not easy to single out any for particular mention, but the process of pill making by machinery would probably appeal most to nine out of ten visitors to the factories.

One sees the pill mass worked up in a capacious mechanical mixer, then automatically rolled into strips, and then again automatically rolled into the conventional little globules. These globules are mechanically sorted for size, and " under sizes " and " over sizes " are automatically rejected and go back again into the pill mass for the automatic process to be repeated.

The coating of pills is done by a device which holds the individual pill by a vacuum, immerses one-half in the coating solution, and then performs a similar operation with the other half of the pill.

One sees also the homely but necessary Seidlitz powder and the morning draught of Erasmus Wills' Salts mechanically compounded and mixed in huge bulk in drums of wonderful capacity and marvellous cleanliness, then mechanically weighed by machines with a daily capacity of some 30,000 quarter-pound tins, packed, and so via the despatch department to the shop counter.

One strolls further and sees vaseline being filled into pots by machinery at the rate of over 30,000 pots during the working day, and emulsions, extracts, mixtures, powders, lozenges and pastilles, and many other preparations all being similarly dealt with in an expeditious manner by efficient machinery, supplemented by equally efficient human aid. These

> herbs and other country messes
> which the neat-handed Phyllis dresses

are, indeed, handled with scrupulous cleanliness and meticulous exactitude by the many hundreds of white overalled girls throughout the various departments.

The manufacture of scents of all varieties and descriptions is another important side of the business. The still used in the manufacture of Eau-de-Cologne has a capacity of 130 gallons. There are also 100-gallon measuring tanks and 135 storage tanks with a capacity of 100 gallons each. This department, in addition, manufactures many varieties of other scents and hair oils, and the fact that the contents are insured for £100,000 gives some idea of the magnitude of the output.

Boots also produce in vast quantities face and talcum powders, tooth pastes, cold creams, vanishing creams and similar products, and it is extremely interesting to watch the careful supervision of all the different phases in the manufacture of these various toilet preparations. An instance of this care in production is the provision made to ensure that all complexion powders are of an impalpable fineness suitable for the most delicate skin. This task is achieved by silk bolting machines and rotary sifters, while the necessary colour grading is performed with the help of machines called edge runners. In the case of tooth pastes the methods adopted are as equally efficient, and so great is the output that manufacture is carried out in batches of half a ton.

Some idea of the magnitude of the output from the Nottingham Laboratories and Factories can be gathered from the fact that over 1¼ million packages are dealt with every week, and 800 tons of Salines, 500 tons of Official Galenicals, 500 tons of Malt Extract and Malt and Oil, 273,000 gallons of Wet Preparations, Emulsions, etc., in the course of a year.

The packing of this great bulk ready for retail distribution requires some 46 millions of labels, handbills, printed wrappers and linings, ten million cartons, twelve and a half million corks, twenty million bottles and jars, fifteen million tins and five tons of string.

Purity and Accuracy Tests.

Reference has already been made to the very large number of analyses performed in the analytical laboratories in the course of a year, and this point will bear further emphasis. Boots leave no stone unturned to ensure the purity and efficiency of all their products. Every package of raw material before being taken into stock is subjected to analysis to ensure that it is what it purports to be, and the material cannot be used until a certificate has been given by the chief analyst. Further, all manufactured products are analysed at various stages of preparation, and when completed are again subject to close scrutiny during packeting or bottling.

Boots technical experts meet regularly in the " Formula Committee " (which is specially charged with the duty of taking care of the quality of Boots products) and together scrutinise most carefully the formulas, the processes of manufacture, analytical standards, and labels with the directions for use, etc., with the dual object of ensuring that Boots products are of the finest possible quality and that they are presented to the public with adequate instructions for their safe use in the home.

A National Asset.

As already mentioned, in the course of a year the analytical laboratories make some 70,000 analyses, and it is in these analytical laboratories that Boots possess a wonderfully efficient instrument from which the public reaps a great benefit. Not only is an exceptionally high standard of purity guaranteed in all pharmaceutical products to the advantage of the individual purchasers in the Boots shops, but the experimental work which is continually going on is of incalculable value to the nation at large. In the best sense of the word the Boots laboratories are a National asset.

The founder of the firm, Sir Jesse Boot, was a visionary in the matter of the scientific control of pharmaceutical manufacture, and it is simple historical fact that he established a laboratory for the analytical control of the products of his firm at a time when the authoritative standards of the British Pharmacopœia were what we now think perfunctory, and when practically no other house in the trade considered such a safeguard either necessary or financially possible.

Boots War Record.

This steadfast faith in the necessity of a scientific basis for pharmaceutical manufacture stood the firm in good stead when, in the early days of the war, the manufacture of chemicals heretofore never produced in England was undertaken with striking success. The firm became the pioneer in this country of large-scale production of fine pharmaceutical chemicals.

BOOTS PURE DRUG CO LTD

The Fine Chemical Works.

The plain tale of the achievements of the Boots organisation during that trying period is a record of remarkable and conspicuous service. In collaboration with the Anti-Gas Department of the Ministry of Munitions it produced the first effective box respirators ever used, and supplied the whole of the chemical granules for filling the respirators used by the British and certain of the Allied Armies during the whole period of the war. In addition the firm filled and supplied upwards of 8,000,000 complete box respirators to the British and Allied Armies. Contemporaneously the manufacture of saccharin was being worked out at the behest of the Sugar Commission, and Boots became, and still are, the largest producers of this useful sweetener in the United Kingdom.

These then novel activities soon called for the services of a laboratory devoted solely to the higher branches of chemical research, the result of which establishment has amply justified the foresight shown. The highly trained personnel soon found themselves hampered in their work by a lack of suitable research chemicals, formerly imported entirely from certain firms specialising in them in Germany, and the problem of a home supply was attacked. So successfully have the research chemists of the firm applied themselves to this task that it has been found possible to publish a list of 800 research chemicals issued by the firm which enjoy increasing popularity in the laboratories of the universities and scientific institutions of the country.

An Improved "Salvarsan."

A further striking indication of the value to the Nation of the work carried on in the Boots Research Laboratories is afforded by the Company's experience in the early days of the war in the matter of Salvarsan. A shortage of Salvarsan had early manifested itself when German supplies were cut off, and as a result of the valuable research work carried out by the company's chemists a licence for the use of enemy patents had been granted to the firm by the Board of Trade.

Not content, however, to be mere copyists, the research staff discovered a much superior product, which, while being at least equally effective as an anti-syphilitic was much less toxic in effect, and could be presented in the form of a solution for easy administration. This preparation, covered by letters patent granted to the Company and called "Stabilarsan," enjoys an increasing sale and is the last word in anti-syphilitic technology.

The newer antiseptics, such as Chloramine T., Proflavine and Acriflavine were produced early in the history of the Chemical works, and such products as aspirin and chloroform are staple manufactures. Fine alkaloids and delicate active principles such as Atropine, Hyoscyamine, Caffeine, Digitalin and Capsaicin are also regular products of the works.

The New Diabetes Remedy.

The most recent instance of the determination of the Boots organisation to maintain its position as leader in the newer therapy is its enterprise in the production of "Insulin," the new remedy for certain forms of diabetes. Intensive research work has resulted in the production of a product of remarkable activity which has undergone clinical tests at one of the most important of the London hospitals for some considerable time past. The good results obtained encourage the hope that we are on the threshold of a revolution in the treatment of this hitherto fatal disease, and the Company is fully alive to the possibilities open to it in virtue of its enlightened view of its responsibilities in face of this great advance in medical science.

The firm is one of the very few licensed by the Medical Research Council for the production of this important product, and its set policy is by diligent and intensive research work to retain its proud position in the production of the medicaments of the newer therapeutics.

That it will succeed in its endeavour to give a lead not only in this direction, but also in its declared intention to maintain the honoured traditions of pharmacy, none who come into close contact with the business can for one moment doubt. An executive with vision and foresight, adequate and conservative finance, and a staff of enthusiastic and experienced workers is a triple alliance of indisputable strength.

DRUG AND DISPENSING DEPARTMENT AT BOOTS THE CHEMISTS' BRANCH, ROYAL EXCHANGE, MANCHESTER.

A 13,000 Staff.

And one is inclined to think that not the least potent factor in the combination is the great reserve of productive energy and good-will provided by the employees of the concern. Approximately 13,000 people are employed by the Boots Companies, and of these over 1,000 are qualified men in charge of the retail shops and of various departments at the manufacturing end of the business. We have already noticed the spirit of enthusiasm which animates all grades of workers at the Nottingham headquarters, and the same esprit de corps is to be found at the branch shops. Instances of long years of service with the firm are frequent, and employees of twenty years' standing are quite numerous. This seems satisfactory enough testimony to the conditions of employment and the interest shown by the executive in the personal welfare of the staff.

The Staff Welfare Movement.

Boots do not render mere lip-service in the matter of staff welfare. Much time and thought is devoted to the relationships between employer and employee, and the Welfare Council forms a most valuable link between the workpeople and executive. Broadly, the welfare activities may be divided into three categories—medical, educational and recreational.

As regards the first of these, provision is made for minor mishaps by first-aid rooms established throughout the factories, each room being in charge of a qualified nurse. In addition there is a central surgery with a doctor, trained nurse, V.A.D. nurse and a masseuse. And further, in order to keep in touch with employees who may fall ill, two trained nurses are employed to visit their homes to offer advice and assistance.

To meet the great need for Holiday and Convalescent Homes at reasonable rates the Company have purchased a large house at Skegness, the popular holiday resort on the East Coast, while a Convalescent Home in North Wales is provided by Boots Health Insurance Society.

Educational and Recreational Facilities.

The educational side of the Welfare Movement provides that all employees between the ages of 14 and 16 may attend four hours per week during work time at the Continuation School, where the training includes English, house management, gymnastics, mathematics and drawing. Selected pupils from the Continuation School are allowed to continue training during work time from 16 to 18. Further, the evening school fees for students attending regularly are refunded by the firm at the close of the session. Other facilities offered include special lectures and day scholarships at the University.

The recreational aspect of the Welfare Movement is particularly active. The firm have provided 11 acres of playing fields, including 18 tennis courts, two bowling greens, skittle alley, two cricket pitches, quoit bed and a putting course. A large pavilion with seven dressing rooms, baths, tea rooms, kitchen, larder and accommodation for a residential caretaker was built last summer.

There is also an institute with billiard room, games room, smoke room and large room for dancing and social gatherings. These were provided by the firm and are under the control of an Institute Committee elected by the employees.

Further, there is a commodious modern Swedish gymnasium with spring floor, complete with the latest equipment. It may be mentioned that this gymnasium is in constant use for day classes in the day Continuation School, and for evening classes for employees. The 42nd Nottingham Troop of Boy Scouts is comprised of members of the firm, the Company assisting by the provision of rooms, camping equipment, band instruments, and so on, while there are two large girls' choirs and a weekly hobbies club. The Welfare Organisation also published "The Beacon," a social magazine for the employees.

In addition to these mentioned activities Boots assume a moral responsibility for the well-being of their employees. Thus should any individual worker find him or herself in difficulties he or she may

SURGICAL DEPARTMENT AT BOOTS THE CHEMISTS' BRANCH, CARDIFF.

A VIEW OF BOOTS SPORTS GROUNDS, LADY BAY, NOTTINGHAM.

make an appeal to the Welfare Council with the certainty that the appeal will receive sympathetic consideration, and assistance be forthcoming if the circumstances warrant it.

An Entente Cordiale.

It will therefore be seen that the relationships between the Boots Companies and their employees are far from being soulless transactions in the buying and selling of labour. The management on their part seek in every way to create a favourable working atmosphere and recognise that they have other obligations to their workpeople beyond the paying of wages.

On the other hand, the employees respond right well to a treatment which they believe is actuated not so much with the idea of amassing further profits, but is rather the outcome of sane thinking as to what should be the real attitude of an employer toward his workpeople.

The Future of "Boots."

In concluding this survey of the present-day activities of the Boots concern it may perhaps be interesting to look a little ahead and consider what the future has in store for the undertaking.

As a great manufacturing organisation retailing its products directly to the consumer, its chief care would seem to be the ensuring of a market for those products. The manufacturing end of the business may, we think, well be left to take care of itself. Housed as it is in modern buildings, equipped with plenty of efficient plant and served by the best technical advisers and workers, it could speed up production both economically and with little, if any, outlay of capital.

As regards the retailing side of the business, this is equally efficient and elastic, and is capable of expansion along safe and sure lines.

At the present time there are nearly seven hundred branch shops open, and the policy is to endeavour to open one new shop each week. If this rate of expansion were adhered to there would, of course, be a continuous increase in the sale of the Boots products, while the field for the establishment of further branch shops would by no means be fully cultivated for a good many years to come.

The existing branches are well placed throughout the country and vary in size and importance from the small branches in the lesser populated provincial towns employing three or four assistants, to those fine examples of modern-day chemists' shops such as are represented by the Regent-street branch in the West End of London, the Church-street, Liverpool branch, and the Royal Exchange, Manchester establishment, which employ as many as 70 or 80 assistants each.

For one or other class of branch there are yet many openings, and that the directors are keenly alive not only to the possibilities of establishing new branches, but to developing the business of those already existing, is shown by the recent installation at a large number of shops of surgical departments under the supervision of trained nurses. In these surgical departments a full range of appliances, dressings, nursery requisites and so on is available, and this innovation should considerably augment the Company's gross turn-over.

Eighty Million Customers.

Last year the Boots shops catered for some eighty millions of customers, which is practically equivalent to saying that each of the inhabitants of England, Scotland and Wales was served twice in the course of the year. Bearing this factor in mind and contrasting with the figure of 1911, when 38,000,000 customers entered the Boots shops, it will be seen that the business is wonderfully progressive.

With an industrial revival and a consequent appreciation in the spending power of many millions of people, one would expect last year's record to be easily eclipsed. In any case, such is the initiative and energy behind the organisation that one seems quite safe in saying that the "Boots" of to-morrow will not be the "Boots" of to-day. Sane industrial enterprise and solid development and progress are essential to the Nation's welfare, and to those ideals the great "Boots" undertaking will, we may be sure, not fail to contribute substantially in the future.

An Address

ON

SOME CHANGES IN OBSTETRIC PRACTICE

SINCE THE FOUNDATION OF THE MEDICAL SOCIETY OF LONDON.

Delivered before the Society on Oct. 8th

By HERBERT R. SPENCER, M.D.,
F.R.C.P. Lond.,
OBSTETRIC PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL; PRESIDENT OF THE MEDICAL SOCIETY OF LONDON.

As medical societies and medical men advance in years I think it is useful to cast their view backwards on the past in order the better to appreciate the present and to order the future. In order to review the history of a subject of present interest, I propose to consider some changes in obstetric practice, particularly in dealing with cases of contracted pelvis, which have occurred during the 150 years of the lifetime of our Society.

The Medical Society of London was founded in 1773, at an important period in the history of British midwifery. The renaissance of midwifery occurred later in England than in continental countries, and dated from the publication in 1651 of William Harvey's "De generatione animalium" with the chapter on labour, which was the first original English work on midwifery. The conservative principles and the observation of nature which Harvey advocated had been carried on by a succession of teachers, of whom Smellie—one of the greatest obstetricians of all times and countries—had died only ten years before the Medical Society was founded; he was succeeded by William Hunter, Denman, Osborn, and others.

The practice of midwifery during the preceding century was slowly passing into the hands of men-midwives since Clément had been ennobled by Louis XIV. and appointed "accoucheur" to Madame la Vallière in 1673. The advice of Harvey to imitate Nature, "who is a perfect operatrix," had been in the main followed by British obstetricians, who have always considered the interests of the mother superior to those of the child. This attitude, which is indubitably the best for cases where the pelvis and child are of normal dimensions, led to the death of many children and mothers when it came to be applied in cases of contracted pelvis. For cases of slight contraction the powers of Nature were often sufficient, aided by the "hanging-legs" position of the mother (Scipione Mercurio, 1595). Version—an ancient operation revived by Ambroise Paré and recommended by Harvey "when there is necessity for handiwork in the business"—and forceps, invented by Chamberlen and greatly improved by Levret, Smellie, and Benjamin Pugh, proved unsatisfactory when serious contraction of the pelvis had to be dealt with. Experience has shown that these measures involve considerable risk to the mother and child; and the dreadful alternative, embryotomy, necessitates the sacrifice of the child.

Eighteenth Century Advances in the Study of the Contracted Pelvis.

At this time important advances were made in the study of the contracted pelvis. Smellie, in 1754, had first given a representation of the rickety pelvis. At the same time he measured the diagonal conjugate of the pelvis, and R. W. Johnson, in 1769, published his method of direct measurement of the true conjugate diameter with the hand. In 1772 Stein published a description of his internal pelvimeter, and in 1775 Baudelocque described his instrument, which is still used for the measurement of the external diameters of the pelvis. Smellie's plates (published in 1754) and W. Hunter's "Gravid Uterus" (1774) raised the artistic representation of pregnancy and labour to the highest point of excellence. Sir Fielding Ould, who was master of the Rotunda Hospital from 1760–66, made the first observations on the entrance of the head into the pelvis and laid the foundations of the "mechanism of labour." He pointed out the danger of the high forceps operation in cases of contracted pelvis, invented an instrument (the "terebra occulta") for perforating the child's head, and stigmatised Cæsarean section as "a detestable, barbarous, illegal piece of inhumanity."

At this time, too, there was a great movement in the world towards the development of the special study of obstetrics. Lying-in hospitals and chairs of obstetric medicine were being founded, particularly in Italy. At Padua, where Harvey had studied, a chair of obstetrics was instituted in 1769. In Vienna extensive lying-in wards were being built in the Allgemeine Krankenhaus, and were opened in 1784.

L. J. Boër.

In 1786 Lucas Johann Boër (1751–1835) went to study in Paris under Baudelocque, Lauverjat, and others. After spending 15 months in Paris he came in 1787 to England, where he studied under Denman, Caborn, Clarke, and Lowder. His travels in Great Britain, where midwifery was conducted on conservative—or at least expectant—lines following the teaching of Harvey, Smellie, and W. Hunter, made a great impression on Boër; "he had learnt in France what art, in England what nature could do." He carried out his conservative principles while professor of the lying-in wards of the great General Infirmary in Vienna, which he raised to the first position in Europe. Boër held the chair of obstetrics in Vienna for 33 years. In 2926 labours he only employed the forceps 19 times and perforated the head eight times. He laid down very strict rules for the artificial interference with labour, insisting that this should only be resorted to in cases of necessity and then in the gentlest and most suitable manner; "all artificial means apart from strict necessity are mere bungling, involving the risk of torturing and destroying mother and child." While Boër was in Paris he saw the patient Souchot, on whom Sigault had performed symphyseotomy; she was suffering many discomforts as a result of the operation—the uterus was prolapsed, the pubic joint was ununited, and there was incontinence of urine from a fistula. On the continent other attempts were made to solve the difficulty of the contracted pelvis by symphyseotomy and by Cæsarean section, but the results of these operations were not such as to commend them to the British obstetricians.

Lucas's Restricted Diet.

Measures directed towards the mother having proved unsatisfactory, an ingenious attempt to overcome the difficulty of labour in contracted pelves by procuring a small child by restricting the diet of the mother was made by James Lucas, surgeon at the Leeds General Infirmary. His paper was read before the Medical Society of London on Sept. 8th, 1788, was communicated by our founder, J. C. Lettsom, and is printed in the second volume of the Memoirs of the Medical Society of London (1794). The treatment consisted in "temperance in diet, a diminution in the usual quantity and a change in the quality of the food, an increase in exercise, the occasional loss of a few ounces of blood, and the moderate use of cooling aperients. This regimen was more strictly enjoined in the last months of pregnancy from a persuasion that an observance of it in the former months would avail little if neglected in the latter."

Lucas mentions a case of contracted pelvis where embryotomy had been performed in the two previous labours; under his treatment the next labour was remarkably less tedious and the child was delivered without difficulty. He gives other instances of the benefit of this treatment. This method of starving the mother to diminish the size of the child is usually attributed to Prochownick, who published a paper on the subject in 1901. It is interesting to find that it was first published by the Medical Society of London more than a century before. The method, of course, has its limitations and is very rarely employed at the present day, but I have recently seen a patient who was successfully delivered in America of a small child after adopting the treatment recommended by Lucas.

SYMPHYSEOTOMY AND PUBIOTOMY.

In the year 1772 Jean René Sigault published a paper, "An in Partu Contra Naturam Sectio Symphysis Ossium Pubis Sectione Cæsarea promptior et tutior?" Five years later, on Oct. 1st, 1777, he first performed the operation on a patient named Souchot, delivering her of a living child, the mother recovering with the discomforts and inconveniences already mentioned. The Faculty of Medicine of Paris had a medal struck in Sigault's honour, and in many directions there was great enthusiasm over the operation. But next year, in 1778, Piet reported that he had previously delivered the patient Souchot of a large child with prolapse of the cord without much difficulty, and thus took away a little of the credit of Sigault's achievement. Gradually the enthusiasm died down on the continent, and in England the operation was looked on with disfavour, mainly owing to the researches and writings of the Hunters and Denman. The first time this operation was performed in England was in 1782, by Welchman (*Lond. Med. Journal* for March, 1790). The child was dead and the mother succumbed. It was only in Italy that the operation continued to be performed, and that sporadically, till it was revived by Morisani in 1881 and by Pinard in 1900; the latter in 100 operations had a mortality of 12 per cent. for the mothers and 13 per cent. for the children.

Since that date the division of the symphysis and its modification pubiotomy have been extensively practised on the continent, and to a less extent in this country, with a gradually diminishing rate of mortality. The reason why it has not been more in favour is that it inflicts considerable injuries on the mother, and has a higher rate of mortality for the child than Cæsarean section. It has the advantage that in a doubtful case it permits a trial of the effects of labour without increasing the risk of the operation, and may be employed in a limited class of cases of slight pelvic contraction. In this country, however, the enthusiasm of some of its advocates appears to have evaporated. I have never performed the operation, and am of opinion that it is very rarely indicated if the cases of contracted pelvis are properly investigated during pregnancy. The disadvantages of symphyseotomy and pubiotomy have led to other operations for enlarging the pelvic cavity, such as excision of the pubic bones and of the sacral promontory; but these operations have not led to any practical results.

INDUCTION OF PREMATURE LABOUR.

Of this life-saving operation, purely English in origin, we have the first account in Denman's Introduction to the Practice of Midwifery.[1] It was given to Denman by Dr. C. Kelly, who informed him that "about the year 1756 there was a consultation of the most eminent men in London at that time, to consider the moral rectitude of, and advantages which might be expected from the practice, which met with their general approbation. The first case in which it was deemed necessary and proper fell under the care of Dr. Macaulay, and it terminated successfully. The patient was the wife of a linen-draper in the Strand. Dr. Kelly had himself performed the operation three times on the same woman, and twice the children had been born living." Denman defines the limitation of the operation in these words: "It is in those cases only in which there is a reduction of the pelvis to a certain degree and not beyond that degree that this operation ought to be proposed or can succeed." He mentions the case of a lady of title who had had four dead children at term. Labour was induced early in the eighth month of her pregnancy and the child was born alive and survived. Denman induced premature labour by puncturing the membranes, and stated his opinion that the operation is perfectly safe to the person on whom it may be performed. Puncture of the membranes is still used by some obstetricians—e.g., v. Herff—as a means of inducing labour; but the favourite method is the bougie method, first employed by Sir J. Simpson in 1854. It is usually described as Krause's method; Krause's publication, like Simpson's, is dated 1855.

The induction of premature labour has always remained an essentially British and mainly English operation. In France it was opposed by the great authorities Baudelocque and Capuron, and not till 1830 was it favoured by Stolz. In Paris it was first performed by P. Dubois in 1840, but was condemned on insufficient grounds by Pinard in 1900. In Germany Wiedmann wrote in its favour in 1779; his pupil Wenzel was the first to perform it in 1804, and his paper, with Froriep's commendation, led to its adoption in Germany, where it is still practised, but is by no means a favourite operation. In Berlin it was first employed by v. Siebold in 1819. In the Scandinavian countries it was not performed till the year 1827. In America, Whitridge Williams, of Johns Hopkins Hospital, Baltimore, states that he has never found it necessary to resort to the induction of premature labour in contracted pelvis. His erroneous reasoning in adopting this attitude has been pointed out by Dr. Herbert Williamson in an excellent article.[2] I will only add here that in his alternative treatment by Cæsarean section Dr. Whitridge Williams finds it necessary to resort to the mutilation of the mother by hysterectomy with remarkable frequency.

From this brief historical review of the induction of premature labour it will be seen that the operation has met with little favour on the continent of Europe and in America. If one inquires into the cause it is found in three factors—that the operation has been performed in unsuitable cases, at unsuitable times, and by unsuitable means. The cases of contracted pelvis suitable for the induction of premature labour are those with a true conjugate diameter of not less than 3¼ inches; the operation should not be undertaken before the thirty-fifth week from the last day of the last menstruation, and the bougie method of Simpson or rupture of the membranes is the best method for ordinary cases. Champetier de Ribes's bag may be required in special cases; though it has a great disadvantage (amongst others) that it displaces the presenting part. For a pelvis with a conjugate diameter less than 3¼ inches in length Cæsarean section is more suitable, though I have delivered by induction at the thirty-fifth week through a pelvis with a 3-inch conjugate a child who grew up to womanhood. The mother died some years later after an operation for cancer.

Carried out in the manner indicated, induction of premature labour is an excellent operation, giving results to the child less favourable indeed than Cæsarean section, but giving results to the mother even better than those of natural labour at term. The operation has been repeated in one of my cases 12 times, with the result of 12 living children. The larger the pelvis over the 3¼-inch minimum the later the induction should be deferred, but for pelves with a 3¾-inch true conjugate it is better generally to let the patient go to term unless the head is unusually large. It is important that the delivery of the premature child be left to the natural powers, forceps and version being particularly injurious to these infants. Having had a large experience of this beneficial operation, having watched the upgrowing of some of these premature girls to normal womanhood and motherhood, it is more in sorrow than in anger that I see the unpopularity of the operation with many foreign obstetricians, and their failure to follow the three simple rules, above enumerated which are essential for success.

Antisepsis and Anæsthesia.

Before I proceed to consider Cæsarean section for contracted pelvis it may be well to review the development of the antiseptic treatment which has revolutionised this and other operations. In 1772 Charles White, of Manchester, published a treatise on the "Management of Pregnant and Lying-in Women." In this work White speaks of puerperal fever as a putrid fever which is contagious and arises from putrefaction of retained products or from the air of lying-in wards. White's contribution to the study and treatment of puerperal fever was important, and has been dealt with very fully by Prof. Adami in his Lloyd Roberts Lecture.

In 1843 Oliver Wendell Holmes published in the *Quarterly Journal of Medicine and Surgery* a paper on "the contagiousness of puerperal fever," in which he adduces strong evidence of the contagiousness of the disease and points out effective means of preventing it. He specially mentions changing the clothes and washing the hands with chloride of lime after visiting cases of puerperal fever; he reports that by adopting these precautions a doctor was able to attend other cases of labour which ran a perfectly normal course. In 1846 Ignaz P. Semmelweis became assistant in the lying-in wards of the General Hospital in Vienna. From 1784 to 1822 these wards had been under the care of Zeller (1784–89) and Boër (1789–1822), and the mortality from puerperal fever had been 1·25 per cent. over the whole period. Under Boër's successor, Klein, medical students were allowed to practise anatomy and to dress suppurating wounds while attending cases of labour, and Semmelweis noticed that the mortality was much higher in the wards attended by the medical students than in those attended by the midwives. In the five years before Semmelweis's appointment the mortality in the students' wards had risen from 6·56 to 9·92, while that in the midwives' wards had fallen from 5·58 to 3·38. Semmelweis adopted the method of washing the hands with chloride of lime with the result that the rate of mortality fell from 8·3 to 2·3 per cent. It is the undying merit of Semmelweis to have pointed out that puerperal fever arose not only from infection from corpses, but from any putrefying organic substances. What putrefaction was due to was shown by the researches of Pasteur in 1860, and Lister in 1867 gave to the world his antiseptic treatment which laid the foundations of the modern aseptic surgery by which the danger has been almost completely removed from operations which a few years ago were uniformly fatal.

The introduction of anæsthesia by means of ether (Morton, 1846) and chloroform (Sir James Simpson, 1847) was one of the greatest advances ever made in medicine. For prolonged operations, I think there can be no doubt that ether is preferable; but in ordinary midwifery cases chloroform, administered *à la reine*, is still the best and safest means of alleviating the pains of labour and it is excellent, administered until the child is delivered, in cases of the classical Cæsarean section. The attempt to produce painless labour by the injection of scopolamine and morphia has not proved successful, and is not free from danger to mother and child.

Cæsarean Section.

Cæsarean section has always been interesting, and never more so than at the present day. The origin of the word Cæsarean is unknown. On the supposed birth of Julius Cæsar by means of this operation, based on an error in the translation of a passage in Pliny, Sacombe has given his opinion in the following terms: "Pliny was a lying historian whom it would have cost no more to split the belly of Aurelia with his pen in order to deliver Cæsar than to split the rocks with vinegar to open up a way across the Alps for the troops of Hannibal."

The first volume of the memoirs of the Medical Society of London contains a most learned paper in the form of a letter addressed to Lettsom on the character of Æsculapius. The writer of the letter describes the birth of Æsculapius by Cæsarean section as mentioned in Ovid's Metamorphoses,

natum flammis uteroque parentis
Eripuit geminique tulit Chironis in antrum.

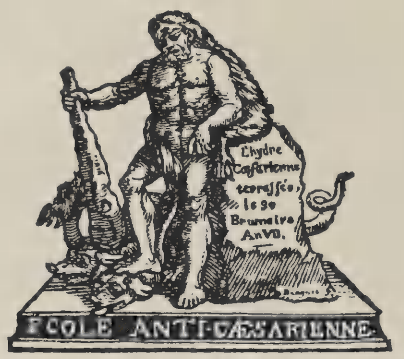
Despite these illustrious examples Cæsarean section attained but little popularity until the end of the eighteenth century, although it had been practised on the continent, with only occasional success. In England it was 20 years after the foundation of our Society, in 1793, that the first successful operation was performed on a living woman by Barlow, of Bolton; the child did not survive. Ambroise Paré (1510–90), having seen two Cæsarean sections performed by his pupil, Guillemeau, with fatal results to the mothers, was opposed to the operation. "Je ne conseillerai jamais de faire tel œuvre où il y a si grand péril sans nul espoir." In 1581 Rousset had published the first work on the subject under the title, "Hysterotomotokie." In 1595 Scipione Mercurio had recommended the operation. He had seen patients on whom it had been performed in Toulouse, where he said it was as well known as bleeding for headache. He gave an illustration of the operation and recommended that the incision should be made to the right of the middle line in order to avoid the spleen.

At the time our Society was founded there was a widespread desire amongst obstetricians to avoid the horrible craniotomy which at the end of the eighteenth century was performed frequently, especially in England. The most eminent of these obstetricians was Jean Louis Baudelocque. In 1796 Baudelocque performed Cæsarean section on a patient who had previously had a living child at term; the patient died three days after the operation. As a result of this unfortunate experience Baudelocque was assailed with the most violent obloquy by Jean François Sacombe, an eloquent, witty, and scurrilous charlatan who occupies such a remarkable position in the history of Cæsarean section that a few particulars of his career may be worth mentioning.

J. F. Sacombe.

Sacombe was born about the year 1750 at Carcassone. After studying obstetrics at Montpellier and in England under Osborn and W. Hunter, he went to Paris to practise as an accoucheur. He gave out that he could deliver any patient with his hand alone, without the use of any instrument. He was especially bitter against those who performed Cæsarean section, and from the year 1790 onwards he disseminated his views by lectures, pamphlets, and posters. In one of the pamphlets he pilloried Baudelocque as a "murderer," for which libel he was condemned to pay a fine of 3000 francs. Unable to pay the fine he fled from Paris, but returned under the altered name of Lacombe in 1813. Having lost his obstetric practice he gained a living by selling secret remedies. "Deserted by Lucina, he paid attention to Venus," wrote a work entitled "Venusalgia," and died discredited and neglected in 1822. In order to carry on his campaign against Cæsarean section, Sacombe founded his "École anticæsarienne" in 1798. Here lectures were given and an annual festival was held at which a silver medal was awarded to one of the pupils; on one side of the medal was the figure of Hercules slaying the Hydra, with the inscription, "No more Cæsarean section"; on the other side a beehive and flying bees, and the inscription "Sacombe's anti-Cæsarean School." The recipient of the medal had the privilege of embracing Madame Sacombe. A statute of Bonaparte was set up in the school, and Sacombe dedicated one of his works to him, and at one time praised the Consul for "muzzling the Cæsarean tigers." In 1815, however, he was imprisoned for writing against the Emperor. Sacombe was a prolific writer, both in prose and verse. In his "Lucine française" (1803) he gives an account of François Rousset, whose work in Cæsarean section had been highly praised by Haller and Portal. Several faculties of medicine had disputed the glory of conferring a degree on Rousset, and Catherine de Médicis had appointed him her physician. "However, I resolved," says Sacombe, "to overturn this colossal statue, to break it and to prove to my pupils that celebrity in medicine can only be desirable when based on talents and virtue. I will demonstrate that Rousset was neither a physician nor a surgeon, but a fanatic and ignorant criminal, and the vile instrument of depopulation of which the infamous Catherine de Médicis made use against the Protestants."

FIG. 1.



En-tête appearing above the foreword to J. F. Sacombe's "Elémens de la science des accouchemens," published at Paris, Germinal an X. (1802).

In his "Elémens de la science des accouchemens" (1802) he styles himself "professeur de médecine et de chirurgie des accouchemens," yet he speaks contemptuously of accoucheurs as "hermaphrodites of the art" and "midwives in breeches." Of Clément, the first "accoucheur," he writes:—

> Clément dut au hazard sa vogue et son crédit
> Il enrichit moins l'art que l'art ne l'enrichit.
> Accoucheur des Laïs, en dépit de Lucine
> Clément fit fortune où maint amant se ruine."

Sacombe's "Elémens" contains a portrait of the author and a plate of the École Anti-Cæsarienne, with a figure of the Cæsarean Hydra struck down 30 brumaire, an vii. (Fig. 1). Of this monster he writes: "Born in the midst of the civil wars which desolated France towards the middle of the sixteenth century the Cæsarean Hydra, attracted by the odour of human blood, has raised again its hideous head amidst the scaffolds which crowned the soil of France at the end of the eighteenth century." He ends his work: "My task is complete; I have avenged nature and consoled humanity in giving the death-blow to the Cæsarean Hydra."

It was, however, not by the École Anti-Cæsarienne nor its discredited founder, but by the almost uniformly fatal results of the operation at the end of the eighteenth century, that the performance of Cæsarean section was rendered infrequent.

Modern Cæsarean Section.

In 1866 Murphy found that of 56 operations in Great Britain 46 had terminated fatally (82 per cent.). Even as late as 1874 the maternal mortality was 54 per cent. in Europe and America. In 1876 Porro introduced his method of amputating the uterus after the section. The effect of this, combined with Lister's antiseptic method, was to lower the death-rate considerably, so that in Truzzi's great collection of all the "Porro" operations published up to 1901, the death-rate was reduced to 24·8 per cent. In 1882 Sänger introduced his method of suture, which still remains the favourite, and though various modifications have since been recommended, such as the incision into the lower segment and the subperitoneal and transperitoneal incisions, the Sänger conservative method, with silk sutures carefully buried by a continuous peritoneal stitch, has advantages over other methods in uninfected cases. The advantages of the Sänger incision and suture are: (1) The rapid delivery of the child in an unasphyxiated condition; (2) the operation can be repeated with safety; (3) adhesions and rupture are rare if the wound be properly sutured with silk.

The results of the modern Cæsarean section in non-infected cases are highly satisfactory. Thus, Routh, in 1910, found a maternal mortality of 2·9 per cent. in "clean" cases, of 10·8 per cent. in cases with ruptured membranes, and of 34·3 per cent. in cases where frequent examinations or attempts at delivery had been made. From those and from figures collected by Holland (who dealt with hospital cases only) it is seen that to obtain a low mortality rate it is necessary that the mothers should not be infected when operated on. In such cases the operation should be free from mortality and in my personal practice has been so.

The safety of the operation in skilled hands has led to great abuse by its performance in cases in which it is quite unnecessary and often quite unsuitable. I have known it proposed for a patient with a large pelvis, solely because she was 38 years of age; she was easily delivered by nature of a 9 lb. child. When we read of hospital staffs and even individuals performing 100 Cæsarean sections in a year, it is time to make a protest against unnecessary operative interference. The most marked instance of "meddlesome midwivery" is contained in a work by I. W. Potter, entitled "The Place of Version in Obstetrics" (1922). This author delivered 1130 women in the year ending August 31st, 1921; of these 100 were delivered by Cæsarean section, and 938 were delivered

FIG. 2.

Obverse and reverse of medal struck in honour of Edoardo Porro in 1901 to commemorate the twenty-fifth anniversary of his first hysterectomy following Cæsarean section.

by version. It is to be regretted that such a line of practice should be advocated, as it will inevitably be attended with disaster in the hands of less skilful imitators.

Francis Bacon commends as excellent for the advancement of learning the keeping of Registers of Doubts, with the caution that "when the doubts be thoroughly sifted and brought to resolution, they be from henceforth omitted, discarded, and not continued to cherish and encourage men in doubting." In obstetrics there have been many doubts. But doubt that natural labour is in ordinary cases preferable to operative labour should have been discarded long ago.

In June, 1923, there appeared[3] a thoughtful and remarkable article on Cæsarean section, in which the author says, "in the minds of certain obstetricians and surgeons Cæsarean section is the only method by which a self-respecting patient can be delivered and maintain her standing in the community." He also states "that the mortality statistics of Massachusetts show that of the women dying during pregnancy and labour in a given period approximately one-third die of complications which have been treated by Cæsarean section." Finally, the writer of the article appeals for protection for women in childbirth against the ill-judged enthusiasm of the untrained obstetrician. Cæsarean section, to which Sacombe thought he had put an end in 1798, has shown marked evidence of revival, and his hydra has developed heads non-existent in his day. The performance of Cæsarean section for cases of placenta prævia, accidental hæmorrhage, malpresentations, and eclampsia is being overdone, though not to the same extent as for "contracted pelvis."

It is sad that such a beneficial operation as Cæsarean section, which has been developed to such a pitch of perfection that a woman, however deformed, can be delivered with safety to herself and child, should be brought into discredit by being performed in cases for which it is unnecessary.

I have endeavoured to show some of the changes which have occurred in the treatment of contracted pelvis in the lifetime of the Medical Society of London. Further improvement of the treatment depends on more accurate measurement of the pelvis and fœtal head, probably by means of X rays. Every woman should have her pelvis measured to see if she is fitted for childbearing. During pregnancy she should be examined at the thirty-fourth week to ascertain the presentation of the child and its size relative to that of the pelvis. If the pelvis is contracted, it should be treated by one of the methods suitable for the particular case. Of these methods at the present time, in my opinion, induction of premature labour is employed too little and Cæsarean section too much.

As opinions are of less value than facts, I give the results of three years' practice at University College Hospital, where the routine mentioned above has been adopted. In the three years (1920, 1921, and 1922) 5647 women were delivered. Of these premature labour was induced for contracted pelvis 113 times, all the mothers and 101 of the children surviving; Cæsarean section for contracted pelvis was performed 32 times, all the mothers and 30 children surviving. Craniotomy was performed four times (twice for dead children and twice for hydrocephalus); the four mothers recovered. Forceps were used, for various reasons, 168 times—i.e., in less than 3 per cent. of the cases—all the mothers recovering. I am indebted to the obstetric registrar, Mr. Leslie Williams, for these figures.

Cæsarean section entails risk of hernia, of adhesions, and of rupture in subsequent pregnancy. These risks are probably avoidable in aseptic cases by proper suturing and sutures; their magnitude can only be ascertained when obstetricians publish all their cases instead of a selection of cases done in favourable conditions before or in the early stages of labour, later cases being treated by craniotomy or hysterectomy. The sterilisation of a woman after Cæsarean section in an uncomplicated aseptic case is, in my opinion, not justifiable; in complicated cases hysterectomy is sometimes required.

In conclusion, I hope I may be pardoned for bringing a somewhat technical subject before the Medical Society of London. In the past some hard things have been said of obstetricians; in recent days, however, they have been commended as integrators of medicine. Agreeing with Sir Clifford Allbutt as to the importance of that integration, I have placed my views before a Society which, by its constitution and practice, is the best example of the advantage to be derived from discussion of medical subjects by physicians, surgeons, and general practitioners.

An Address

ON

MANIPULATIVE SURGERY.

Delivered before the Section of Orthopædics of the Royal Society of Medicine on Oct. 2nd

BY R. C. ELMSLIE, M.S. LOND., F.R.C.S. ENG.,

PRESIDENT OF THE SECTION.

THE use of manipulative methods in surgery is constantly being brought before the public and has perhaps been specially prominent during recent years. It is a branch of work frequently taken up by unqualified practitioners, probably because it is easily acquired and can be carried out with comparatively little training or experience and with very considerable immunity from gross accidents. Formerly such practitioners were called "bonesetters," claiming that they replaced small bones in the course of their manipulations. Wharton Hood states that Hutton really believed that he did this. This term, "bonesetter," is a very ancient one and was formerly applied to both regular and irregular practitioners. In the seventeenth century there was a "bonesetter" and an "assistant bonesetter" on the staff at St. Bartholomew's, both of them presumably surgeons. Recently, however, the irregular practitioner has become known as a "manipulative surgeon," rather than as a "bonesetter." The claim to replace small bones is difficult to sustain in view of the knowledge of anatomy now possessed by many of the general public and of the possibility of confirmation by X ray photographs. It is now more often made by the comparatively new school of osteopathists, rare still in this country, but very numerous in America. These practitioners, in spite of radiography, are able to propound their claims to replace bones in the comparatively complicated osteology of the spine.

Sir James Paget investigated bonesetting, and published a clinical essay upon the subject in 1867. His teaching was followed up by Howard Marsh, who lectured almost yearly at St. Bartholomew's upon the subject. The following paragraph from Howard Marsh's writings is worthy of quotation, as it puts many of the facts in a nutshell:

> "Chirurgery, or handicraft, began, as we may well believe, in attempts to pull-in dislocated bones, to straighten distorted joints, and to restore movement to stiff limbs. In this dawn of the art nothing was known of anatomy or pathology; it was only seen that a limb was bent or stiff, and force was employed to overcome the defect, just as it might be used to straighten a crooked bar, or loosen a rusty lock. Soon, however, the primitive operators of those early days became ranged in two groups: the mere empirics, who went straight to the point of trying what force would do; and those who endeavoured to ascertain the nature of particular cases and the difference between one case and another—those, in other words, who cultivated pathology and diagnosis in order that they might use force with safety and advantage. The results of practice conducted on these different lines can easily be imagined. The empirics, applying force in all cases alike, and thus

involving their patients in a mere game of chance, did good whenever such untempered force as they could use was appropriate, and harm whenever it was unsuitable; those who used force only when they could see a reason for doing so, and when they thought it was safe, while they did little harm, often, as their diagnosis was very rudimentary, missed an opportunity of producing a cure. In these conditions the empirics frequently had the best of it. Regular, but as yet very ill-informed, practitioners were so often beaten in their encounters with disease that they lost credit in the public eye; while the empirics, making the most of their cures, and not seldom laying the blame of their failures on the surgeon whose previous treatment they alleged had done all the mischief, were credited with powers that approached the miraculous. And we can understand their success, for every surgeon now well knows that instances are common enough in which pain and limited motion, resulting from sprains and other injuries, may at once be set right by even rough and unskilled movements, or, indeed, by an accidental wrench."

Wharton Hood, gaining experience from working with the bonesetter, Hutton, showed how some of the methods of treatment of injuries formerly in general use led to the production of stiff joints which could be easily righted by simple manipulation. More rational methods of treating injuries, together with the evolution of a well-trained and experienced body of masseuses, have greatly diminished the number of cases of gross stiffness of joints after injury, the class of case most often quoted by Paget, Marsh, and Wharton Hood. Yet the dramatic successes of the unqualified manipulator continue, and it behoves the medical profession to look to its methods and to find out why so many of these cases pass into the hands of the unqualified.

Factors in Favour of the Unqualified Practitioner.

Certain external factors must inevitably work in favour of the unqualified. Of these one of the principal is the inherent tendency of the public to believe that the irregular practitioner must have some peculiar ability, either a special skill in methods of manipulation unknown to the profession, or an almost occult power of seeing what is wrong inside or what is the effect of his manipulations. A second factor is the unrestricted power of the unqualified to advertise, either directly or through the mouths of their patients. A third is perhaps the most important: it is that the failures of the unqualified are in almost every case hidden. The patient who visits a bonesetter and is cured boasts of the fact widely, but those who are not cured or who are made worse are perhaps a little ashamed that they have been gulled, they say nothing of their experience, unless perhaps to a medical man who subsequently treats them, and who discreetly maintains silence. For the failures of the unqualified manipulator are numerous, almost as numerous as his successes. The gross cases quoted by Marsh, who mentions two cases of sarcoma and one of spinal caries treated by manipulation, are perhaps uncommon at the present day. Yet I personally have seen many failures by commission or omission. Among the former I may mention myositis ossificans around the knee, rendered so bad by the manipulations of a bonesetter that the patient had to submit to complete rest of the joint for two and a half years before movement returned; a youth with a slight spinal injury subjected to manipulation of the coccyx, which was loosened, and the patient converted into a confirmed neurasthenic with coccydynia; a young woman converted by osteopathic manipulation into an apparently hopeless neurasthenic; and a woman with a large loose body in the knee which was manipulated into such a position that it blocked full extension of the knee for four years.

I need only mention more gross cases of obvious fraud, the treatment of a joint with bony ankylosis by manipulations repeated over a period of a year, the patient being promised a restoration of mobility; a dislocated thumb treated for three months with improvement of movement *in the direction of excessive hyperextension;* and a shoulder stated by a bonesetter to be dislocated, whereas it was normal; when confronted with an X ray showing the joint in place, he countered with the X ray of a dislocated shoulder, which he demonstrated as the normal position.

Errors of omission are also not uncommon. The unqualified manipulator refuses to treat a patient on the ground that the condition does not come within his province and a cure subsequently results from a simple manipulation carried out by a qualified medical man. In addition to these, cases in which manipulation has failed to cure the original condition or in which there is a recurrence of trouble (for example, displacement of a damaged semilunar cartilage) come within the experience of most of us. I do not suggest that the bonesetter is to be blamed for this last class of failure. Usually in these cases he has carried out a rational method of treatment. If his patient has any complaint to make, it is because he has been promised a certain cure where no certainty was possible. But when the failure is due to insufficient care in diagnosis, or to an inadequate knowledge of pathology, or to the use of irrational methods, then the manipulator should be blamed.

We all have our failures; medicine is not an exact science, and no doubt many of us have failed to cure patients who have subsequently been successfully dealt with by the unqualified manipulator, just as some of us fail to cure patients who are afterwards cured by our colleagues, or as the unqualified manipulator has failed to cure patients with whom we afterwards succeed. The real interest of the profession, and particularly of the orthopædic surgeon, is to frame such rules of treatment as will leave as small as possible a number of cases for the unqualified manipulator to treat.

Suggestions for the Orthopædic Surgeon.

Looking back in my own practice I venture to make these suggestions to you all. First and foremost, in treating all bone, joint, and muscle injuries, first form as accurate as possible a judgment of the pathology of the condition present. When there is an inflammation or other condition indicating rest and contraindicating mobilisation, say so. If your judgment is accurate, your patient will not be cured by a practitioner who takes up the opposite view. A common error is to assume that the inflammatory reaction to a simple injury necessitates rest. This is not so; a sprain, provided that an important ligament is not ruptured or unduly stretched, recovers most rapidly with normal use, the joint being supported if necessary. An injury to a small portion of muscle requires use as soon as the pain felt will permit it. If the internal semilunar cartilage in the knee has been damaged and displaced, use of the knee as soon as possible after the displacement has been reduced is the best method of treatment. Some years ago I had to treat an oarsman in training for an important boatrace who displaced the internal semilunar cartilage nine days before the race. The displacement was reduced 12 hours after it occurred, and the patient was only kept out of his boat for 24 hours. In the end he rowed with an apparently normal knee and has had no trouble since. This leads me to a second point. Never advise operation for removal of a semilunar cartilage which has been once displaced and successfully reduced; in a large number of cases the accident never recurs.

One often meets with patients who give a history of recurrent trouble with a knee which sounds superficially like a displaced cartilage, but in whom true locking of the knee has been absent. It is my custom to treat all these cases by manipulation, warning the patient that if the cartilage is damaged there may be a recurrence of the trouble necessitating operation. I believe that many of the so-called cartilage injuries cured by bonesetters come into this class, and that there has never been any damage to the cartilage at all. Other cases so cured are analogous to those in which the cartilage is displaced once and once only. In them the cartilage is presumably displaced by the manipulation into a position in which it gives no trouble and is not liable to become again displaced. I do not believe that the bonesetter has any special tricks of manipulation. If he has, he ought to describe them instead of keeping his knowledge to himself, just as any of us would put on record any new method we had devised. But, as I say, I do not believe that he has any such methods, and this opinion is borne out by the fact that many of us have treated patients with cartilage injuries which have been manipulated by bonesetters not simply once but many times.

It would take me too long to enumerate the many other conditions amenable to treatment by manipulation; they range from joints and muscles painful on account of apparently trivial restriction of movement, to gross cases of stiff joints, of adherent muscles, and of nerves such as the sciatic, which are fibrosed after a long-standing neuritis. I can only make this suggestion, that whenever there is a possibility of improvement by well-judged manipulation, try it. If your pathology is correct, you will do no harm and often you will cure your patient. I do not suggest that you can always promise a cure; how much you can promise must always depend upon individual knowledge and experience. Further, I would say that whenever a joint or muscle is apparently normal, yet painful, it is worth while to try a manipulation. Disease and mechanical defect having been eliminated, no possible harm can result, and in nine cases out of ten some minor adhesions, undetectable by clinical examination, will be felt to give and the patient will be cured.

I believe that we fail to cure by manipulation most often by our failure to give the method a trial. Let us use it freely, restrained only by an adequate knowledge of pathology.

THE RELATION OF GASTRIC ULCER TO CARCINOMA.*

By JOHN MORLEY, Ch.M. Manch., F.R.C.S. Eng.,
HON. ASSISTANT SURGEON, MANCHESTER ROYAL INFIRMARY; HON. CONSULTING SURGEON, ANCOATS HOSPITAL; LECTURER IN APPLIED ANATOMY, MANCHESTER UNIVERSITY.

The modern doctrine that gastric ulcer frequently undergoes cancerous degeneration, or, conversely, that cancer of the stomach very commonly originates in simple chronic ulcer, has derived most of its authority from workers in the Mayo Clinic. The vast quantity of clinical and pathological material at Rochester, the high level of achievement there in the taking and digesting of case records, and the number of skilled pathologists working in closest contact with the surgeons, all combine to give a power of compiling statistics on such a scale as to command the almost envious respect of the rest of the surgical world.

U.S.A. Literature.

W. J. Mayo,[1] in 1907, stated that "in 54 per cent. of the 69 cases of cancer of the stomach operated upon in 1905 by Dr. C. H. Mayo and myself, the clinical histories and pathologic examinations of removed specimens made it certain that the cancer had its origin in ulcer." In 1909, Wilson and MacCarty,[2] pathologists to St. Mary's Hospital, Rochester, published a report on 218 specimens of resection for ulcer or cancer, 210 being gastric. Excluding a few rarities like gastric adenoma, they found in the material 47 simple ulcers. "Of the 158 cases remaining 5 were ulcers with suspicious aberrant epithelial proliferation, and were labelled 'doubtful.' Of 153 cases of undoubted cancer left, 109 (71 per cent.) gave enough gross and microscopic evidence of previous ulcer to warrant labelling them 'cancer developing on ulcer.' In 11 other cases (7 per cent.) there was considerable evidence of preceding ulcer, but not enough to warrant placing them in the former group. In only 22 per cent. was there little or no pathological evidence of preceding ulcer." In May, 1910, MacCarty[3] quoted his earlier conclusions that 71 per cent. of cases of cancer of the stomach are associated with a definite ulcer, and added, "68 per cent. of the resected ulcers of the stomach, including the duodenal ulcer which rarely becomes malignant, were associated with carcinoma."

Wilson and McDowell,[4] in 1914, in a paper based on 339 cases of resected gastric ulcer, gave further statistics of somewhat similar import, and stated: "It seems probable that gastric cancer rarely develops except at the site of a previous ulcerative lesion of the mucosa." In a paper published in 1920 MacCarty[5] used these words: "Most chronic gastric ulcers larger than 2 cm. in diameter are carcinomatous. The converse of this is not true, because many chronic gastric ulcers smaller than 2 cm. in diameter are carcinomatous."

British Literature.

Among the leading British authorities on the subject Sherren,[7] writing in 1920, quotes three cases of gastric ulcer in which he did a simple gastro-enterostomy, who died of carcinoma seven, five, and four years after operation, though it would appear possible that two of these may have been malignant from the first. He states that in 135 ulcers removed with a diagnosis of simple ulcer, showing no malignancy to the naked eye, 6 (or 4·4 per cent.) showed carcinoma starting in the edge of a simple ulcer on microscopical examination. He adds: "In 57 gastrectomies for cancer, 14 (or 25 per cent.) showed definite microscopic evidence that the malignant disease started in the edge of a chronic simple ulcer." Moynihan,[8] in his recent Hunterian Lecture, says: "Of the cases of cancer of the stomach that I see upon the operation table a steady average of two out of three give a past history that is extremely suggestive of gastric ulcer." He states that in 18·5 per cent. of his excised chronic ulcers, giving no naked eye suspicion of malignancy, one edge of the ulcer only shows early malignant change. (This 18·5 per cent. is a somewhat striking contrast to Sherren's 4·4 per cent.) Walton,[12] in a series of 150 cases of cancer, found evidence of preceding simple ulcer in 45.

We see, then, that these three authorities lend their powerful support, if to a somewhat modified extent, to the teachings of the Mayo Clinic on the subject. H. J. Paterson,[9] on the other hand, is entirely sceptical, and regards the matter as not proven. He states his own experience that only 1 per cent. of the patients on whom gastro-enterostomy is performed for simple ulcer die later of cancer. Spilsbury[10] summarises his conclusions on the morbid histology as follows: "There are commonly found at the edge of the ulcer gland cells which have penetrated deeply into the scar tissue and are cut off from the regenerating glands. They may exhibit an atypical glandular arrangement, or may form narrow columns of cells; isolated cells are also seen. It is these cells detached from the regenerating epithelium and buried in the fibrous tissue of the ulcer which are sometimes referred to as pre-cancerous, and which, from their position and irregular arrangement, are regarded by others as indicating a malignant transformation in the ulcer. It is owing to this interpretation having been placed on the cells by the investigators at the Mayo Clinic that they report a percentage of 68 of the presumed peptic ulcers removed by operation as showing microscopical evidence of malignancy." Spilsbury concludes that malignant transformation of a peptic ulcer must be an uncommon event.

A Scandinavian View.

An important paper on the subject by N. A. Nielsen[11] appeared last year in the *Acta Chirurgica Scandinavica.* Nielsen believes that there is no possibility of agreement on the histological evidence, and turns to the clinical side of the problem. His conclusions are based on a series of 221 ulcer patients, followed for a period of 2½–19 years after the completion of a course of medical treatment. He found that of these 221 patients, 155 had had ulcer symptoms for more than six years, and in this group two only developed cancer. Of 66 patients with ulcer symptoms under six years in duration no fewer than ten developed cancer. This striking contrast Nielsen explains by arguing that the ten cases that died of cancer under six years after the onset of their ulcer symptoms were ulcer-simulating cancers from the beginning, and he concludes that a patient suffering from simple ulcer has no greater liability to cancer of the stomach than an ordinary individual.

---

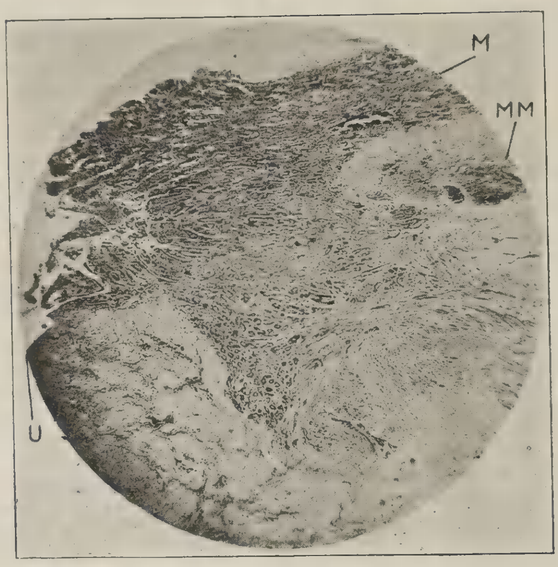
* Read before the Manchester Surgical Society.

The weakness of Nielsen's very careful investigation lies in his material. Only 92 of his 221 patients were operated on, and the remaining 129 were diagnosed on clinical grounds alone. They would therefore almost certainly include some cases of extra-gastric lesions simulating ulcer, and as Nielsen himself admits, a considerable number of duodenal ulcers. I do not think that this criticism vitiates Nielsen's conclusion, but it does undoubtedly deprive his results to some extent of statistical precision.

Terms of Present Investigation: Classification of Material.

I have set myself in this investigation to determine whether the clinical and histological data in my own small series of cases support or contradict the findings of the Mayo Clinic pathologists that 71 per cent. of cases of cancer of the stomach originate in simple ulcer, and that 68 per cent. of apparent simple ulcers are microscopically cancerous. I desired, in other words, to determine whether a patient suffering from chronic gastric ulcer is in graver danger of developing cancer of the stomach than an average healthy person of similar age.

FIG. 1.



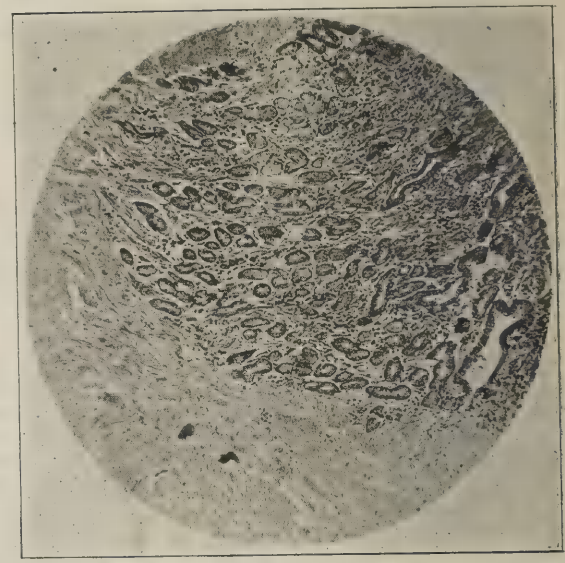
Microphotograph showing edge of simple ulcer with irregular gland tubules drawn below level of muscularis mucosæ by scar tissue. M, mucosa. MM, muscularis mucosæ. U, base of ulcer.

The cases on which my conclusions are based have been under my own care, and the records have all been taken by me personally or by residents under my direct supervision. In all cases I can vouch for the accuracy of the histories and all relevant details. The cases fall naturally into three groups. Group 1 is a series of 50 cases of chronic gastric ulcers, removed either by partial gastrectomy or local excision. I considered them all simple ulcers on naked-eye examination after removal, and they have all been subjected to careful microscopical examination. Group 2 is a small series, supplementary to Group 1, of ten chronic ulcers treated by simple gastro-enterostomy. Group 3 is a series of 56 cases of clinically proved cancer of the stomach. These three groups will now be discussed in detail.

Group 1.—In collecting this series of 50 chronic ulcers I have carefully excluded cases of duodenal or pyloric ulcer, for I agree entirely with Moynihan's opinion that almost all cases of so-called pyloric ulcer are really in the first part of the duodenum, and no one claims that duodenal ulcers frequently undergo cancerous degeneration. The pre-pyloric ulcer, on the other hand, is definitely gastric, and is usually separated by at least ½ inch from the pyloric ring. One gastro-jejunal ulcer has been included in the series. The method of dealing with the specimens has been as follows. The stomachs, after removal (and all except two were partial gastrectomies), have been stuffed with cotton-wool to preserve their shape, and fixed in Kaiserling fluid. They have then been slit open, usually along the greater curvature, and as many blocks as seemed necessary have been cut, and a rough diagram made to show the position of the blocks in the stomachs. This part of the work has been done in most cases by Dr. J. H. Dible, lecturer in pathology at the Manchester University.

The results of the histological examination of these 50 cases must now be described. Five cases proved to be definitely malignant on microscopical examination, and form a small but highly important subdivision which will be described in detail below. Of the remaining 45 cases, 6 showed irregularity of the glandular epithelium at the edge of the ulcer, which might conceivably be held to indicate the earliest phase of a malignant transformation. In one case this change takes the form of a branching, almost papillomatous arrangement. In 4 there is some irregularity of the arrangement of cells in the tubules at the edge of the ulcer, but what is of more importance, an apparent invasion by some tubules below the line of the muscularis mucosæ (Figs. 1 and 2). Transgression by glandular epithelium across the line of the muscularis mucosæ I take to be the first indisputable evidence of cancer in a gastric lesion; but in these 4 cases the grouping of tubules in their suspicious surroundings is so similar in arrangement and so circumscribed in extent that I have formed the opinion quite definitely that it is merely an infolding of the epithelial edge by scar tissue in an attempt at healing, and is not evidence

FIG. 2.



A higher magnification of the irregular epithelium shown in Fig. 1.

of a malignant change. The remaining one of this group of 6 suspicious ulcers shows a cluster of tubules under the muscularis mucosæ at a point far removed from a large and perfectly simple ulcer. I am sure that this appearance is due to an irregular depression in the mucosa, and only include it in the group to drop it out again. The duration of ulcer symptoms in the other 5 cases was 16, 1, 7, 12, and 4 years respectively.

We have, therefore, in this group 5 definite cancers, 5 ulcers which some might suppose to be early cancers, but which I consider to be healing simple ulcers, and 40 simple ulcers which I believe no competent morbid histologist could accuse of malignancy.

I must now describe very briefly the five cases of definite cancer in this group:—

CASE 1.—Male aged 33. Five years' history of pain two hours after food, at first in periodic attacks lasting a week, with intervals of five or six weeks. The last 12 months pain has been felt daily, being relieved by food. Has been vomiting and losing weight lately. Appetite good, but fears to eat. X ray examination showed a filling defect in prepyloric area, which Dr. J. M. W. Morison, the radiologist, thought most probably due to a simple ulcer.

Operation.—Operating with an open mind as to its malignancy, I found a hard mass on the lesser curvature near the pylorus looking very like a growth as seen from the outside, with minute white nodules on the peritoneum a short distance from the main mass. Gastrectomy was performed, but on opening the stomach after removal there was a shallow ulcer, with none of the characteristic raised everted edge of cancer, but a hypertrophic mass of what I took to be scar tissue on the outer coats. The specimen was sent to Dr. Dible as a chronic simple ulcer, and he reported as follows: "Your clinical instinct was a better guide than your post-operative opinion, for it is a malignant growth undergoing ulceration. There is very widespread penetration by the tumour tissue. The little nodules on the pyloric antrum are malignant deposits. All of this goes to suggest that the two conditions, ulcer and cancer, are in such a case in no way connected, except that the malignant growth sooner or later undergoes ulceration. From the appearance of the sections I should say that the prognosis is very bad."

Thirteen months afterwards this patient returned to see me with a secondary deposit in the umbilicus and palpable nodules in the peritoneum.

CASE 2.—Male aged 40. History of seven years' pain, two to three hours after food, in periodic attacks at first. Pain more continuous the last 12 months, with loss of weight and appetite. X ray examination showed pyloric obstruction, and the pylorus and duodenum were not outlined.

First Operation.—A large hard ulcer was found extending from the pylorus some 2 inches along the lesser curvature, with almost complete pyloric obstruction. The ulcer was considered malignant, and a posterior gastro-enterostomy performed.

Second Operation.—Three weeks later the pyloric half of the stomach was resected by the Billroth 2 method. The ulcer seen from the interior after removal appeared to be a large chronic simple one, with dense fibrosis round, but sections showed definite cancer.

The patient did remarkably well at first, but died two years later with recurrence in the liver.

CASE 3.—Male aged 61. Two years' history of pain two and a half hours after food, relieved by taking more food. Little vomiting. Appetite fairly good. Great loss of weight latterly. Previous health good, except for liability to bilious headaches. He never had stomach pains before the last two years. On examination there was a vaguely palpable tumour in the epigastrium. X ray examination showed a filling defect of the pylorus.

Operation.—A hard mass was disclosed in the pyloric region. A Polya gastrectomy was done, and to the naked eye after removal it was doubtful whether the large ulcer present was simple or malignant. Microscopical examination showed an ulcerating adeno-carcinoma with a marked fibrous reaction round it.

This man was operated on over three years ago and is still in good health, with no sign of a recurrence.

CASE 4.—Male aged 66. Two years' history of pain one hour after food, periodical at first and relieved by vomiting. Much emaciation of late. The preoperative diagnosis was simple ulcer.

Operation.—A mass was found extending from the pylorus along the lesser curvature, which was considered to be malignant. Partial gastrectomy was done, and an ulcer with a deep crater was found, which I thought was probably simple. Dr. W. B. Anderton examined it and found it was an adeno-carcinoma.

It should be noted that the age at operation of these four cases was 33, 40, 61, and 66, while they had been ill 5, 7, 2, and 2 years respectively. The four cases are of great interest in our present discussion. They all simulated simple ulcer in their clinical history, in that the pain was periodic, occurred some long time after food, and was relieved for a time by taking food, while the appetite in most was good. But I can find nothing in the clinical histories or the histology to suggest that they were cancers originating in simple ulcer. I would maintain rather that they were slow-growing ulcerating cancers of a type that simulates simple ulcer, and that they were cancers from the first. I do not believe that the onset in the last few months of continuous pain, vomiting, and emaciation meant a change from simple to malignant ulcers. A much more probable explanation is that these symptoms meant the development of pyloric obstruction. The presence of scar tissue in the base of an ulcer cannot be accepted as evidence of an old inflammatory lesion, for in cancer of many parts of the body, such as, for example, the breast or colon, scar tissue abounds.

CASE 5.—This case is somewhat different in character. A female, aged 31, gave a history of ten years' periodic attacks of pain after food. Two years ago she was explored by a well-known surgeon with a provisional diagnosis of gastric ulcer. He examined the stomach carefully, but could find no trace of ulcer, and removed a chronically inflamed appendix. Relief after the operation was of short duration. The symptoms returned, and for the last few months before she was referred to me she had had unmistakable symptoms of pyloric obstruction. When I saw her there was a palpable sausage-shaped tumour at the pylorus, unusually smooth and soft for cancer, and visible peristalsis. She was losing weight rapidly, vomiting all her food, and had evidently almost complete pyloric obstruction.

Operation.—I found what felt like a firm fleshy growth involving the pyloric half of the stomach, with enlarged coronary and suprapyloric glands. I did a very extensive gastrectomy, and on slitting the stomach up afterwards found multiple ulcers of the mucosa throughout the pyloric half, with only islands of mucous membrane left between them, while the palpable tumour appeared to be due to an enormous hypertrophy of the muscular wall in the pyloric region, secondary to a cicatricial pyloric stenosis. Once again the microscope disproved the naked-eye diagnosis. It was an intensely active spheroidal-celled cancer, with great tendency to ulcerate. But I cannot accept this as a case of cancer following ulcer, for a careful exploration two years before had disclosed no sign of ulcer, and I think it much more probable that the indigestion of eight years' standing before that exploration was reflex pylorospasm, probably originating in the appendix, and that the cancer was a later and, so to speak, accidental development.

Group 2.—This small series of ten cases is soon dealt with. It consists of 10 cases of chronic ulcer in which simple gastro-enterostomy was done, and the ulcer left in situ. The duration of pre-operative ulcer symptoms averaged 9·3 years, and the average age of onset was 31·1 years. Both these figures, as will be shown below, correspond very closely with those of Group 1, and afford a similar contrast with the cancer group. But such material is not very conclusive in our present inquiry unless followed for a large number of years after operation. Of these 10 cases, 1 was well for a year and then relapsed and died of hæmatemesis in the medical wards of the Royal Infirmary, when post-mortem examination showed an active simple ulcer; 1 was in good health for five years and then died of lung trouble without any gastric symptoms; the other 8 cases are alive and well 4, 6, 4, 3, 10, 10, 9, and 1 year after operation.

Group 3.—This group consists of 56 cases of clinically proved cancer of the stomach, and it is necessary in the first place to set forth the evidence in favour of the accuracy of the diagnosis. Forty-six of these cases were operated on, but in only 11 was I able to do a gastrectomy, and I have only been able to trace the specimens and microscopical sections, the final proof, in 9. Almost all of those operated on without removal of the growth, however, showed, besides the primary growth in the stomach, definite and advanced metastases either in the glands, the peritoneum, or the liver. I think, therefore, that there was no possibility of error in the diagnosis of the 46 cases operated on. Of the remaining 10 of the series, in 4 the clinical diagnosis, in each case based on a characteristic history with a large palpable mass in the stomach, was confirmed by X ray examination. In the remaining 6 cases there was a characteristic tumour in the epigastrium, with, in all but one case, secondary masses in the liver or omentum, and in the one case without them the history and the palpable tumour were typical of cancer of the body of the stomach. I have carefully excluded a number of cases in which the evidence in support of the diagnosis was not quite conclusive, or in which the records were incomplete, and I have no doubt that all the 56 cases were genuine cancers of the stomach.

Results in Group 3.—The main purpose of this group is to determine whether there was clinical evidence of previous ulcer in a large proportion of the cases, and the result is somewhat striking. In 52 cases there was no history of previous indigestion before the onset of the symptoms of cancer. Of the remaining four cases one had an illness ten years before which was diagnosed as gastric ulcer, and had been quite well after that until 12 months before operation, when her cancer symptoms began. One had attacks of indigestion for ten years before operation, but no hæmatemesis. One gave a history of liability to painless bilious attacks for years. Of one it was simply recorded that he had had years of indigestion. In only three of the 56 cases, therefore, did the clinical history afford any evidence at all of a preceding simple ulcer, and in all three the evidence was inconclusive. The arbitrary division in point of time between the "history of present illness" and "history of previous indigestion" must vary greatly with the different writers on the subject. To summarise a case, as some authors do, in some such words as "History of previous ulcer two years," or "History of cancer nine months," seems to me to be straining our credulity, since it is so much more probable, in a case of gastric cancer with a total history of two or three years' illness, that symptoms have been due to cancer from the first.

Groups 1 and 3 Compared.

The best argument I can bring in favour of this view is to compare the average duration of gastric symptoms in the cases of Group 3, the proved cancers, with the 45 cases of simple ulcer in Group 1. In 54 cases of proved cancer of the stomach in which the point is specifically recorded, the average duration of gastric symptoms was 12·7 *months* (the longest being five years and the shortest five months). In the 45 cases of proved simple ulcer in Group 1 (excluding the five cases of cancer), the average duration of pre-operative gastric symptoms was 10·3 *years* (the longest being 33 years and the shortest one year). On comparing the age at which gastric symptoms first appeared we find a marked contrast between the two groups. In the 45 cases of simple ulcer the average age of onset was 32·8 years; whereas in the 56 cancer cases the average age of onset was 49·9 years. There is, therefore, an average difference of 17 years as regards age of onset between the two groups. The sex incidence is similar in the two groups. The ulcer group contains 25 males and 20 females, while the cancer group consists of 33 males and 23 females.

It is a point of some significance that 13 of the 56 cases of cancer simulated ulcer in the periodicity of their attacks during the earlier stages, and in the preservation of a good appetite, with temporary relief from pain on taking food. In all of these cases the duration of cancer symptoms was longer than the average. This group of 13 cases, with the four cases already discussed in Group 1, lends support to the view that there is a not uncommon type of cancer, comparatively slow in growth, for a while at any rate, which is capable of producing practically the same symptoms as those we associate quite empirically with simple ulcer. I regret that test meals have not been done in enough of my cases to determine whether free HCl is retained in the gastric juice of these ulcer-simulating cancers. The chief clinical distinctions between this type of cancer and simple ulcer consist in the rapidly increasing frequency of the attacks, in spite of medical treatment, until they become continuous, and in the wasting, which is generally out of proportion to the degree of pyloric obstruction.

If the arguments that I have based on the material set forth in this paper be accepted, it may be urged that we lose one of the chief justifications for partial gastrectomy as the routine operation for the treatment of chronic gastric ulcer—viz., the danger of eventual malignancy. In my view, however, the operation of partial gastrectomy for ulcer is justified on two very sound grounds. The first is that the difficulty of distinguishing on the operating table between simple chronic ulcer and ulcer-simulating cancer is so great as to be sometimes insuperable. The second is that partial gastrectomy, either by the Polya or the more conservative Schoemaker method, has proved the most efficient means at our disposal for the restoration to normal health of patients suffering from simple chronic ulcer of the stomach.

Summary and Conclusions.

(1) While one cannot deny the possibility of cancer developing in the edge of a chronic gastric ulcer, or in some part of a stomach that is or has been afflicted by a chronic gastric ulcer, this investigation provides no evidence that the development of cancer on gastric ulcer occurs with anything like the frequency claimed by some authorities. The evidence set forth in this paper points to the conclusion that a patient with a chronic simple ulcer of the stomach is little, if at all, more liable to cancer than a healthy individual.

(2) I find that roughly 30 per cent. of cases of cancer of the stomach give rise to symptoms which simulate more or less closely those which we usually associate with simple ulcer, and I hold that it is this ulcer-simulating cancer which is responsible for the belief in the cancerous degeneration of simple ulcers.

I am greatly indebted to Dr. Dible for his expert histological opinion as to the nature of many of the ulcers dealt with in the work described.

GLAUCOMA.[1]

BY G. P. HAWKER, M.D. CAMB.,
SURGEON TO THE WEST OF ENGLAND EYE INFIRMARY, EXETER.

THIS condition of increased intra-ocular pressure, known as glaucoma, is a nightmare to some practitioners, whilst others miss it when the signs are plain. I have not space to discuss the condition at length or to be dogmatic; diagnosis between acute iritis and acute glaucoma is frequently very difficult, whilst the treatment of the two conditions is fundamentally different; but I would give the following advice: When seeing a patient with violent headache and neuralgia over the region of the distribution of the fifth nerve, vomiting, mental disturbance, irregular pulse and mists or light flashes (frequently coloured) in front of the eyes, refrain from diagnosing influenza or a bilious attack, for the sight will be rapidly lost and the eye disorganised. Again, in an elderly person complaining of a gradual loss of sight, do not diagnose cataract until you have looked at the pupil area for the fundus reflex with a reflected light; even then, if the area is largely filled with striæ or other opacities it should be remembered that glaucoma is often associated with cataract, or the lens opacities may be secondary to a chronic glaucoma from interference in its nutrition arising from increased pressure. In either case an oculist should examine the patient while the fundus can still be seen, in order to determine the necessary treatment.

---

[1] Abstract from the presidential address delivered to the Devon and Exeter Medico-Chirurgical Society.

The signs of acute glaucoma frequently merge from those of the more chronic type into the eruptive stage. There are often complaints of the prodromal symptoms of transient mists in front of the eye for a moment, rainbow haloes round lights, neuralgic headaches and loss of near sight, especially in the hypermetrope; these are often the only symptoms in the chronic insidious type of the disease. The acute attack may be precipitated by any extra strain, such as a big meal, too much alcohol, mental or physical overwork, or some illness. The chief symptoms have been already given; the vision fails rapidly and in a few hours only hand-movements may be detected. The lids are puffy and the conjunctiva, both palpebral and ocular, is dusky red from venous congestion; the cornea is steamy and may be insensitive to touch or acutely tender; the anterior chamber is shallow and the iris muddy, with pupil moderately dilated, often oval with the long axis vertical, and not reacting. The deeper parts are not visible, but with the fingers the eyeball feels tense and tender on pressure. In acute iritis the onset is not so sudden; the pupil is small and may be irregular, the anterior chamber not so shallow and the cornea not so steamy.

There is intolerance to light in both conditions, as well as in an acute conjunctivitis, from which they must be distinguished. Thus a good light is essential, notwithstanding the patient's protests. If necessary a drop of 4 per cent. cocaine may be used, which will also help by dilating the pupil if the diagnosis lies between glaucoma and iritis. (In ordinary routine cases for obtaining a view of the fundus a drop of cocaine may be used to dilate the pupil instead of homatropine, which is so often used in elderly people with their small pupils. The effects can be neutralised by a drop of eserine before the patient leaves.) Some form of magnification is necessary and a corneal loupe is invaluable, giving a stereoscopic view, but an ordinary magnifying glass will do, giving an enlarged image of the anterior chamber and the iris. The observer will notice whether the pupil is large or small and irregular, with possible synechiæ and a dull listless iris. It should also be noted whether only the superficial vessels are injected, indicating conjunctivitis, or the deep vessels, or both—in which event the trouble is deep-seated. In the chronic type the pupil may have a crenated edge, but it reacts; a lateral light may show a dull pupil area, but again I would urge you never to diagnose a chronic case until you have thrown a reflected light into the eye. If you have not an ophthalmoscope with you an aural mirror will well take its place. Finally, if you find a hard eyeball and a tied-down pupil remember that a secondary glaucoma may develop after a chronic iritis.

Treatment.

Acute glaucoma having been diagnosed urgent steps are necessary. Instil eserine drops, 4 gr. to the ounce, half a dozen times in an hour, giving one drop in the other eye also. Moist or dry heat should be applied, leeches to the temple, and the patient prepared for an anæsthetic. If in a couple of hours there is not a distinct fall in tension and a contracted pupil, iridectomy must be done.

Some illustrative cases will serve to emphasise the condition.

CASE 1.—Female, aged 60, acute glaucoma treated as influenza; eight weeks ill with sudden vomiting, frontal headaches, and a feeling of cold clay round the eye. No pain in the eye at first; after a fortnight redness and watering and loss of sight. Recently coloured lights in the other eye. Early mental symptoms of wandering. Vision: right, 6/18; left, 2/60. Anterior chamber shallow, cornea steamy, immobile dilated pupil, tension plus two, no fundus view. Would not come into hospital; treated with eserine to both eyes. Two months later iridectomy was done for pain. Would not have the right trephined and ceased coming.

CASE 2.—Male aged 45. Subacute glaucoma missed. Seen Jan. 27th, 1919. Under a doctor since Dec. 30th, 1918, with influenza (?). On Jan. 3rd excruciating pains after seeing rainbows for months. Vision: hand movements either eye, tension plus two. Anterior chamber shallow. Treatment of no use.

The following are cases of chronic glaucoma.

CASE 3.—Male aged 63. Bad sight for years, completely gone from right eye, very little remaining in left. Never anything to call attention to his eyes beyond loss of sight; had had no treatment. Vision: right, hand movements; left, 6/60. Discs pale, cupped, and atrophied. The man's mentality was curious; his mother had bad sight at 60, one brother was blind in one eye and almost blind in the other at 42, and another of the family was quite blind at 40.

CASE 4.—Male aged 67. Insidious glaucoma without symptoms. Two years ago had good sight, gradually lost in right and about 12 months ago in left. No pains and no inflammation. I questioned him closely as to the usual symptoms and could get him to admit none, such as mists, rainbows, &c. He had been on drops for most of the time. Vision: right, perception of light only; left, 4/60. Pupils 3 mm. and sluggish, while the anterior chamber was not shallow. Cups filled three-quarters of the discs. Field on the Bjerrums showed a very enlarged blind spot almost reaching the fixation-point. I trephined the left eye and in a month the vision with a minus 0·75 was 6/36(1) and the field had enlarged to almost double. This case illustrates the fact that myotics are only palliatives and do not cure or stop the disease; the latter can only be done by relief of the choked drainage.

CASE 5.—Male aged 73. Slow absolute glaucoma. Bad sight six to seven years in the right eye and two in the left. Under a doctor for five to six years. Lot of pain in the right at times but none in the left. No rainbows, but flashes of light. Pupils 4 mm. and 3 mm., immobile, right iris greenish and tremulous, left blue. Vision: both perception of light. Both corneæ hazy; tension, right plus 3, left plus 2. No right fundus reflex, the pupil being filled with cataract; while a hazy view of the left disc showed huge cupping and atrophy.

The following are cases of secondary glaucoma.

CASE 6.—Female, aged 73, seen in August, 1919. Came up with running eyes, occipital and vertical headaches, and puffy lids with loss of sight. I found the condition of the lids was due to Donovan's solution which she was taking. Vision: right, 6/24(3); left, 6/12. Opacities in right lens and vitreous and guttate choroiditis in both. Some septic tooth stumps. May, 1920, developed cupping and put on pilocarpine drops. Stopped away for some time but in February, 1921, I trephined. She kept vision well in the left eye, but the cataract increased in the right.

CASE 7.—Female aged 62. Cataract secondary to or accompanying glaucoma. Seen July, 1920. Fourteen days before she thought the sight was alright, but then saw coloured lights and had pain at the back of the right eye. Vision: right and left, 6/12. Anterior chamber moderate, considerable opacities in both lenses, spicules, and haze; deep cups seen through the last-named. Tension with Maclean's tonometer was: right, 30; left, 45. Three months later I did a large iridectomy. There is still a steady increase of cataract, but she still sees 6/24 with either eye.

There is no disease harder to diagnose than chronic glaucoma, and only by weighing all the signs can a decision be made between it and early optic atrophy and retrobulbar neuritis. The field of vision in early glaucoma shows contraction of the nasal side, while in optic atrophy it is concentric. The tension should be taken if possible with a tonometer. In shallow glaucomatous cups the disc is pinkish, while in optic atrophy it is pale. There is, however, always some atrophy of the nerve with a cupped disc, and between this atrophy and simple atrophy with a slight depression there is much scope for error in diagnosis. I have seen a fairly advanced case of glaucoma without any visible change in the disc. Chronic glaucoma is almost as common a cause of loss of sight as cataract, and if you bear it in mind many cases can be treated while there is yet time. Acute glaucoma is comparatively rare.

TWO CASES OF *DIPYLIDIUM CANINUM* IN CHILDREN.

BY JAMES FERGUSON, M.B., CH.B. ST. AND., D.P.H.,
DEMONSTRATOR IN ANATOMY, UNIVERSITY COLLEGE, DUNDEE, UNIVERSITY OF ST. ANDREWS;

AND

G. RANKEN TUDHOPE, M.B., PH.D. ST. AND., D.P.H.,
LECTURER AND ASSISTANT IN PATHOLOGY, UNIVERSITY OF ST. ANDREWS.

Dipylidium caninum (*Tænia cucumerina*), a common intestinal parasite of the dog and cat, may also occur in man. The number of published cases is, nevertheless, so small that new cases are well worth recording. This worm was first found as a parasite in man by Dubois in 1751. Blanchard, in his work on the parasitology of the dipylidium, collected 60 cases from the literature up to 1907; of these cases 75 per cent. occurred in children of 3 years and under. They were distributed as follows: Austria, 3 cases; Denmark, 21; England, 2; France, 4; Germany, 16; Holland, 1; Norway, 1; Russia, 3; Sweden, 1; Switzerland, 7; U.S.A., 1. Since Blanchard's paper occasional new cases have been noted.

Dipylidium caninum, according to Blanchard's description, is 15–45 cm. or more in length. The head is small, with a club-shaped retractile rostellum armed with 3 to 4 rows of hooks. The genitalia are double, with a genital pore on each side of the segment. The uterus is in the form of a reticulum, in the meshes of which the testicular vesicles lie. Later on it breaks up into a large number of independent capsules, each of which encloses several (generally 8 to 15) round eggs. The mature segments and the ripe segments show a marked bulging of their lateral borders, giving them the appearance of cucumber seeds.

The cysticercoid larval form (*Cryptocystis trichodectis*) occurs in certain insects, especially in the louse and flea of the cat and dog.

The details of the two cases we have to record are as follows:—

CASE 1.—Some fragments of tapeworm passed by a child were examined by one of us (G. R. T.) in the pathological department of the University of St. Andrews. The specimen consists of three short ribbons, measuring 12, 10, and 4 cm. in length respectively, as well as several isolated segments. The shortest ribbon is made up of very small segments, apparently from the neighbourhood of the neck. The head, unfortunately, is wanting. In the case of the 10 cm. ribbon the segments are larger and definitely elliptical in shape. The posterior segments of this ribbon, all the segments of the largest ribbon, and the isolated segments, show a marked bulging of their lateral borders which at once recalls the appearance of cucumber seeds. The curious appearance of a chain of seeds which these segments present at once attracts the attention. An examination of segments from the posterior end of the longest ribbon shows the presence of double genitalia, the two genital pores being placed symmetrically on the lateral margins. One of the isolated segments is found to be ripe and contains a large number of capsules, each of which encloses several rounded eggs. Within the eggs one can make out the six hooks of the hexacanth embryo. The characters noted are those of *Dipylidium caninum*, and, even without the examination of the head, there is no doubt that we are dealing with that tapeworm. Prof. J. F. Gemmill, who has been good enough to examine the specimen, confirms the diagnosis.

We are indebted to Dr. J. Sellar, Markinch, Fife, in whose practice the case occurred, for the following clinical notes:—

The patient was a baby, bottle-fed from birth. Links of a tape worm were first observed in the stools during the fifth week of life. Previous to this the child had been restless, fretting, and not sleeping. There seemed to be slight abdominal distension, but motions, pulse, and temperature were all normal. There was no vomiting. Saline enemata, given every other day, were followed (but not at once) by the passing of larger portions of the worm, such as the specimen sent to the laboratory. This continued for about a fortnight, after which no further trace of the worm was seen. The child quickly recovered as soon as the worm was expelled. In the house there was a small Pomeranian dog, which was made much of by the elder child of the family. The mother has since kept the dog away from the children and there has been no further trouble.

CASE 2.—A mother of six children brought her youngest child, a female infant aged 5½ months, to one of us (J. F.) complaining that it was passing tapeworms in its stools. She stated that the child often looked white, that its eyes were often swollen, that the tip of its nose was sometimes red, and that it slept as much as a child of that age should do, but often wriggled when asleep. It was breast-fed for two months, then bottle-fed, cow's milk being used. There were no past illnesses. The stools at times were green and loose, at other times constipated. The child appeared small for its age, but there was no pallor and its eyelids were not puffy when examined. The mother was advised to keep any further segments for examination. Two weeks later several segments were obtained, and were preserved in normal saline solution. The mother mentioned that freshly expelled single segments moved for a short time. This statement was verified. The movement was of a slow curling nature, the segment bending along its transverse axis while its extremities, moving away from the plane in which they were originally lying, tended to approach one another. The shape of the small chains at once excluded *Tænia solium* and *T. mediocanellata.* A single segment transfixed with a pin and held obliquely to the incandescent light showed two opposed pores at the lateral margins near their middle. On questioning the mother it was found that a cat was kept in the house, and that at the age of 2 months the child had been for a period of 21 hours in a friend's house in which there was a dog.

Prof. W. J. Tulloch, of St. Andrews University, to whom we are indebted for detailed examinations of the specimens from this case, states that the segments are those of *Dipylidium caninum.* At a post-mortem examination on the cat he found no intestinal tapeworms. Seven fleas found on the cat's body were examined for cysticercoids, but as only negative results were obtained, the presumption remained that these particular fleas were not infected with the parasite. Unfortunately it was not possible to obtain the dog.

With regard to treatment, in this instance the child's feeds were more carefully regulated. The action of the bowels was modified to some extent by the use of hydrarg. cum creta and ol. ricini. At the same time the vitamin content of the food was increased in an attempt to get the child into better condition before using an anthelmintic. A dose of castor oil was ordered every ten days. This generally resulted in the expulsion of several segments. Although nothing else was done, segments ceased to appear after the age of 7½ months. The head was not obtained. Weight records were not kept regularly, but the child even now, at the age of 11 months, is considerably under normal, her weight being only 18 lb. The mother has noticed steady improvement since the disappearance of segments from the stools. The child is bright and lively when awake, and the stools are now rarely abnormal in character.

Two questions arise in view of the close contact that too frequently exists between children, dogs, and cats in many of the houses in the poorer quarters of our cities. One wonders if Blanchard's figure can be taken as a true index of the case incidence of the infection in human beings, and how far the presence of these parasites may be responsible for the chronic ill-health and poor physique of some of our slum children. Detailed examination of every tapeworm passed by a child would appear to be necessary to settle this question.

The cysticercoid form of dipylidium occurs in the louse and flea of the cat and of the dog. The cat and the dog become infected by swallowing their own lice and fleas while licking their coats. Presumably human beings are similarly infected by accidentally swallowing infected lice or fleas. In view of the proportionally large number of cases in the early years of life prophylaxis demands the exclusion of dogs, cats, fleas, and lice from the living quarters of the house.

THE USE OF INSULIN IN GENERAL PRACTICE.*

BY HUGH MACLEAN, M.D. ABERD., D.SC.,
M.R.C.P. LOND.,
PROFESSOR OF MEDICINE, UNIVERSITY OF LONDON,
ST. THOMAS'S HOSPITAL.

THE value of insulin is now definitely established, for sufficient clinical experience has been obtained to make it certain that nearly all patients suffering from diabetes will benefit from its use. Personally, I have seen nearly a hundred diabetic patients who have been treated with insulin, and in every case, without exception, the result was beneficial; frequently, indeed, it was even dramatic. It is most important that insulin should be used only in the proper type of case, for there are many pathological conditions unsuitable for insulin though glycosuria may be present. If, for instance, a glycosuric patient is really suffering from arterio-sclerotic changes, the clearing up of the glycosuria may not materially relieve the condition. Some time ago I saw a patient who was losing flesh very rapidly and getting steadily weaker day by day. A moderate amount of glycosuria was present, and the medical attendant took the view that the case was one of diabetes. Accordingly, small doses of insulin were given with the result that the sugar disappeared fairly rapidly from the urine, but the patient felt no better. Further examination revealed that the glycosuria was but an unimportant and secondary phenomenon, and that the real cause of the trouble was carcinoma of the stomach. Such cases will undoubtedly occur from time to time, but the failure of insulin under these conditions is only what is to be expected. In my own experience, every subject who was suffering from genuine diabetes derived very great benefit from the use of insulin. Probably, it is safe to prophesy that the more we know about insulin and its therapeutic use, and the more careful we are in choosing suitable cases, the better will be our results.

We have now in our hands a satisfactory remedy for the treatment of diabetes, and the question to be discussed is the important one whether insulin may be safely used by the average general practitioner. To this question different people may give different answers. Insulin, like fire, is a good servant but a bad master, and whatever view is taken, the answer must be based on a fairly wide experience of the use of the remedy in various types of patients. My answer, based on my own experience, is that insulin may *be quite safely used by the general practitioner, and I have no hesitation whatever in saying that it is indeed the duty of the general practitioner to use this remedy.* True, stringent precautions must be taken, and some possible contingencies guarded against, but when certain directions are carefully followed, the clinical use of insulin should give no greater cause for anxiety than the use of any other powerful remedy. The most important point in the employment of insulin is to go ahead very gradually. Whatever methods may be adopted in hospitals and special institutions where the patients are always more or less under skilled control, it is courting disaster to use short cuts in general practice. It must be remembered that insulin, when given carelessly, may actually result in the death of the patient. That insulin when given in excessive amounts will produce a certain train of symptoms is well known, but, fortunately, these symptoms are usually not very severe. It is this action of insulin that has to be guarded against in the routine treatment of diabetic patients. If the suggestions to be brought forward later in this paper are carried out, these symptoms will seldom be in evidence, and ought never to be dangerous. On the other hand, every medical man employing insulin should be thoroughly impressed with the fact that he is using a powerful and dangerous, though easily controlled remedy, and that any neglect on his part may end in disaster. Before giving exact details for the clinical use of insulin it will be necessary to consider shortly the nature of the symptoms which may follow the use of this substance.

Symptoms Produced by Insulin.

The symptoms produced by an overdose of insulin may vary considerably in different patients and even in the same patient at different times, but they generally consist of flushing of the face with sweating, often followed by some degree of pallor. The sweating may be very marked. There is often a sense of constriction about the throat and chest. The patient feels giddy and a marked sense of physical weakness may be present. The limbs are frequently cold, and sometimes the first feature observable is a blanching of the face. In other cases, the initial symptom is a feeling of nervousness or distinct tremulousness, so that the patient cannot coördinate his movements. When he tries to write he sprawls on the paper. In mild cases, the symptoms may be entirely subjective, consisting of nervousness, a feeling of impending disaster or apprehension which the patient cannot explain, or a sense of weakness coming on suddenly.

In children the pulse-rate is frequently accelerated. If the condition is not relieved, the nervous symptoms may become very extreme with intense anxiety and very pronounced emotional disturbances. In very severe cases, sensory and motor aphasia, delirium, and confusion may be present, with collapse and syncope, which may result in a state of unconsciousness. Convulsions, so frequent in the insulin symptoms of rabbits, do not appear to be common in man. Marked increase of muscle tonus with a temporary cataleptic state may be seen occasionally during the return of the patient to consciousness.

The occurrence of these clinical phenomena is associated with the action of insulin in lowering the blood-sugar concentration. When the blood-sugar gets too low, the fact is indicated by the appearance of these symptoms, but it is now certain that patients differ greatly as to the exact blood-sugar percentage that may be present when the symptoms come on. Taking the normal resting blood-sugar as about 0·1 per cent., it would seem that, in certain subjects, even a slight decrease to the region of 0·08 per cent. or so may be associated with insulin symptoms, while in others, a blood-sugar as low as 0·05 per cent. may be present and yet the patient may feel quite well. In a general way, however, it is now established that the train of symptoms induced by insulin do not appear when the blood-sugar is normal or above this, and that they are liable to manifest themselves when the blood-sugar sinks to a subnormal level; the exact level at which they appear depends on some unknown factors present in the patient. The association of these insulin phenomena with a more or less lowered blood-sugar—a hypoglycæmia—is so pronounced that the condition is generally referred to as a hypoglycæmic reaction. It may be taken for granted that when insulin symptoms are in evidence, the lower the blood-sugar the more severe are the symptoms.

Treatment of Insulin Hypoglycæmia.

The symptoms described generally come on from two to four hours after insulin has been given, but, not infrequently, they are observed after four to six hours, and very occasionally up to 10 or 12 hours after injection. If too much time elapses between the giving of insulin and the taking of food, symptoms may be present in less than an hour. Though the symptoms of the hypoglycæmic complex may be very severe, it is fortunate that they respond very easily to treatment. Sugar given by the mouth will very quickly remove the condition, so that there is little or no danger if the patient is carefully warned to take some sugar whenever any symptoms such as those mentioned follow the injection. Any kind of sugar will do, but glucose is perhaps best. Since it is advisable to get sugar into the system as quickly as possible, it is a good plan to keep a glucose solution (say, 50 per cent. strength) ready to hand and to warn the patient that he must always take from 1 to 2 oz. of this when symptoms are present. This amount may be followed by another ounce if the condition does not show definite signs of clearing up in from 15 to 20 minutes. From the practical point of view, it is very convenient to use barley-sugar. The patient eats a stick or two of this whenever any indication of hypoglycæmia occurs. Patients treated with insulin should always have some such carbohydrate as barley-sugar at hand, so that some may be taken whenever they feel the approach of symptoms. Though the patient may not perceive the onset of the first attack, he soons begins to be conscious of the very earliest symptoms in subsequent attacks; by taking sugar he can often prevent their further development. When insulin is given carefully, no serious hypoglycæmic symptoms should ever ensue, but, obviously, if two large doses are injected and the patient becomes unconscious, more drastic treatment is essential. One of the best means to counteract the condition in the unconscious patient is the injection of 1 c.cm. of a 1 in 1000 solution of adrenalin. If consciousness is regained as the result of this injection, sugar ought to be given by mouth. In many cases it may be necessary to inject glucose intravenously after the epinephrin. Up to 200 c.cm. or more of a 20 to 30 per cent. solution may be used. Subcutaneous injection of glucose into the loose tissue of the abdominal wall may be helpful if the facilities for intravenous injection are not immediately available. Glucose may also be passed into the stomach by a tube, but this is frequently not a very easy procedure in an unconscious individual. In any case, the fundamental point is to get glucose into the blood-stream as quickly as possible. A dose of pituitrin (1 c.cm.) given subcutaneously also produces excellent effects. Where collapse is present, it may be necessary to give stimulants such as strychnine and camphor hypodermically and hot coffee per rectum. A hot drink after the recovery of consciousness seems to help the patient.

---

* Introductory address on the Use of Insulin in General Practice, delivered before the Royal Society of Medicine, Section of Therapeutics and Pharmacology, on Tuesday, Oct. 9th.

Though severe cases of hypoglycæmia with loss of consciousness were fairly numerous some time ago, when our knowledge of the action of insulin was very limited, they should never be encountered when the insulin treatment is carried out on the lines to be described below.

Effect of Insulin on the Diabetic Condition.

Insulin acts in tending to restore the diabetic patient to the condition of the normal individual. Apparently, in diabetes, some substance essential for carbohydrate metabolism is missing or present in insufficient amount, and the injection of insulin supplies this missing secretion. Consequently, the therapeutic use of insulin results in a disappearance or lowering of the urinary sugar and ketone bodies. The excessive blood-sugar is also reduced towards the region of the normal level. In subjects whose diets are carefully correlated with the insulin dosage, the blood-sugar may be kept within normal limits, and the urine free from sugar and ketone bodies. Very careful adjustment of diet to insulin dosage is, however, required to produce this effect, and frequent modification, both in diet and insulin, may sometimes be necessary. It may be accepted as a general rule that insulin will produce no deleterious effects as long as glycosuria is present, so that it is easy and safe to regulate the dosage by examination of the urine for sugar. In the use of insulin, blood-sugar estimations are of great value, but experience shows that they are not absolutely essential in the great majority of cases. When the glycosuria disappears, examination of the urine for sugar does not help us any more, and it is at this stage that blood-sugar estimations are of most value, for without the means of ascertaining the blood-sugar content, we are working in the dark. In some patients, also, sugar may disappear from the urine when the blood-sugar is still very high (even as high as 0·3 per cent. or more), and in such cases it is essential to know the condition of the blood. Generally, however, the disappearance of glycosuria indicates that the blood-sugar is below 0·18 per cent. or so; if the urine continues to be persistently sugar-free, experience shows that the blood-sugar is generally much lower than this, and frequently is found to be more or less normal. It seems to be much easier to reduce a high blood-sugar to the normal level than it is to reduce an already normal blood-sugar to a state of hypoglycæmia.

The Type of Case in which Insulin is Indicated.

One of the most important points for the general practitioner is to make certain that he does not attempt to treat an unsuitable case. On the whole, there is little danger in the use of insulin when the case is a suitable one, and there can be no doubt that the greatest danger lies in the possibility that a practically normal patient may be treated with this substance. As a rule, there is little difficulty in arriving at a conclusion as to the advisability or otherwise of using insulin in any given patient. Too frequently the terrible ravages of the diabetic condition are obvious, and in spite of long and careful dietetic treatment, the subject is reduced to an emaciated helpless condition. He passes large amounts of urine containing sugar, acetone, and diacetic acid. He complains of great physical weakness, and presents a pitiable picture. In such cases, it is too obvious that the end cannot be far off unless insulin is used, and no possible doubt as to its necessity can arise. Other patients, however, may give rise to greater difficulties in deciding whether insulin should be used. A very common type of diabetic is the elderly individual who frequently complains of being generally out of sorts with weakness of the legs and a feeling of being below par, but who has few symptoms characteristic of ordinary diabetes. Examination of the urine may show a large amount of sugar, but no ketone bodies or at least only traces of them. There is no emaciation, and the patient may appear to be in quite good condition. Should we use insulin in a case of this kind? The answer is not always easy to give, but the condition, though apparently of no great importance as far as objective symptoms are concerned, should never be neglected. First of all, a careful dietetic régime should be ordered, but if this is not successful in removing the glycosuria and materially reducing the blood-sugar, insulin ought to be employed. In many of these patients there is not much danger of coma, and some of them live to quite an advanced old age, but this condition is so frequently associated at a later period with definite symptoms that it should never be disregarded.

The chief symptoms observed are: (1) eye changes, frequently ending in blindness; (2) neuritis; (3) intense local, and sometimes general, irritation; (4) muscular weakness and nervous instability; (5) trophic changes, such as gangrene of the extremities. Of these the most tragic is blindness. I have seen a large number of patients of this type who had been suffering from marked glycosuria and hyperglycæmia for many years and in whom the eyesight is now practically gone. Much can be done to prevent this tragedy at an early stage of the disease, but once definite symptoms set in they are very difficult indeed to treat.

Neuritis also may be very troublesome, and sometimes local irritation is so extreme that the patient's life is rendered miserable. General weakness and severe local cramp-like pains may also add greatly to the patient's discomfort. Though this type of persistent glycosuria may give rise to little or no trouble, it is impossible to foresee what is likely to happen in any particular individual, and the condition should be controlled if possible. In general, it is most important to make certain that the case is really one of diabetes, or very marked glycosuria with a high blood-sugar content, before giving insulin. If the patient's urine does not give an acetone reaction great care must be exercised, and the possibility of the case being one of renal glycosuria must never be overlooked. In this condition it may be very dangerous indeed to treat a patient with insulin, since the blood-sugar may be already somewhat low. Renal glycosuria can be easily excluded by a sugar-tolerance test carried out in the usual way, but it is more simple to give the patient a dose of 50 g. or so of glucose dissolved in a little water, and to get him to empty his bladder from two and a half to three hours after the ingestion of the glucose. This sample of urine will contain glucose, but a specimen passed after this time should not show glycosuria. Instead of taking glucose, an ordinary meal fairly rich in starchy material may be eaten, and the urine tested, after an interval, in the same way as with glucose. If sugar is not being passed in the urine two and a half to three hours after a glucose or starch meal, the individual is not a suitable patient for insulin, and the condition is probably one of renal glycosuria. As a rule, a patient requiring insulin passes large amounts of acetone and diacetic acid in the urine, but this is not always the case. In this connexion it may be noted that ketone bodies may be present in the urine of any patient, no matter what disease he suffers from, if his diet has been recently changed to one containing much protein and fat with very little carbohydrate. If any real difficulty arises as to the suitability of the patient a blood-sugar estimation will frequently help to settle the matter, for the exact state of matters will then be more or less obvious. Always inquire carefully into the history of the patient, and ascertain whether he has lost weight recently. If he has not been dieted before, and is found to be suffering from diabetes, try the effect of diet before giving insulin. Frequently diet will control the condition and insulin may not be necessary. In young people, however, in whom the disease is often more or less acute and well established, it is perhaps advisable to give insulin in all cases, for this gives the best chance for recovery of the diseased pancreatic cells. Occasionally one sees a patient in whom the diabetic condition appears to be very severe but whose response to diet is extraordinarily good. Here insulin is not indicated. If the above directions are observed, there should be no great difficulty in so arranging that only suitable patients should receive insulin.

Blood-sugar in Insulin Treatment.

It is now generally accepted that insulin does not cure diabetes. While insulin is being administered the symptoms disappear, and the patient regains health and strength, but on stopping the insulin the symptoms return. In the ordinary dietetic treatment of diabetes on the principles suggested by Allen the chief points aimed at were to keep the urine free from sugar and to maintain the blood-sugar as near the normal level as possible. The importance of keeping down the blood-sugar lay in the fact that the damaged pancreatic cells had a better chance to recover when there was not an excessive amount of sugar in the blood. Unfortunately, we had little clinical evidence in the past that the diseased pancreatic cells in severe diabetes ever recovered to any appreciable extent, however carefully dietetic rules were observed. To everyone who has had much experience of diabetes it is but too obvious that the more severe types are essentially progressive in nature, and the modern dietetic treatment, so largely used before the advent of insulin, never succeeded in doing more than postponing the fatal issue in such cases. No doubt, the best chance for the damaged pancreatic tissue to recover its efficiency is afforded when the blood-sugar is kept as nearly normal as possible, and in all methods of treatment this is the ideal to be aimed at. In the past, however, we must confess that the results obtained with diet do not give us great reason for hope that insulin will ever cure diabetes. True, in some instances, when diet was the sole means at our disposal, it was impossible to keep the patient's blood-sugar normal, so that there was no real chance given for recovery, but many diabetic patients, on the other hand, went on for a comparatively long time with normal blood-sugars while taking a diet that was amply sufficient for all their requirements. In spite of this, the symptoms reappeared sooner or later, glycosuria returned, the blood-sugar became impossible to control, and death supervened.

Details of Treatment with Insulin.

Having ascertained that the particular patient to be treated is a suitable case for insulin, the next point is to arrange a diet and to give the patient the necessary amount of insulin to keep his urine sugar-free and, if possible, to keep his blood-sugar within normal limits. Frequently this is easy; at other times it is difficult, and sometimes it is practically impossible. In very severe cases of diabetes it is occasionally found that the amount of insulin necessary to keep the patient sugar-free, when even a minimum diet is prescribed, is very large and quite beyond the financial means of the patient. In such cases the patient, even when passing considerable amounts of sugar, does quite well as a rule as long as insulin is being administered. Here the practical aspect of the question has to be separated from purely theoretical considerations, and, in my opinion, it is better to give the patient a moderately good diet with the maximum amount of insulin, even when such diet produces glycosuria, rather than keep him on a starvation diet on which the glycosuria may be much less or even occasionally absent. In very bad cases of this nature experience over long periods goes to show that increased tolerance for carbohydrate is not likely to result, and it is therefore best to let the patient go on in comparative comfort, rather than subject him indefinitely to conditions of severity amounting almost to torment, without any reasonable chance of deriving benefit from them.

Diets are sometimes given consisting of large amounts of one or two substances, such as fat and vegetables for instance, so that, as far as food is concerned, the last state of the unhappy patient is worse than the first. For short periods such diets may be satisfactory and help materially in eliminating glycosuria, though marked ketosis may be present, but, on the whole, they are quite unnecessary and possess the drawback that patients will not carry on with them for any length of time. Now, in order that the best effects should be obtained, it is essential that the diet and dose of insulin should be carefully correlated, and the best means of bringing this happy combination about is the problem that confronts us in every case we treat. Several different methods have been suggested, but, in my experience, the simplest and most satisfactory in the end is for the medical man to put his patient on to a fixed diet which he calculates will be sufficient for his wants, and then to give increasing doses of insulin until satisfactory results are obtained. This daily dietetic allowance should contain from 10 to 15 calories for every pound the patient weighs. The exact quantity given will naturally depend on various circumstances such as the amount of work the patient is performing and other factors. The protein allowance should be in the neighbourhood of half a gramme or less per pound weight of the patient, while the carbohydrate should be small and the fat content comparatively high. Roughly speaking, the carbohydrate content should not exceed about one-third of the weight of the fat given. Thus, in a patient weighing from 120 to 130 lb., a suitable diet would consist of about 65 to 70 g. of protein with 40 to 50 g. of carbohydrate and 140 to 150 g. of fat, giving a total calorific value of about 1700 to 1800. Sometimes, of course, it will be found that considerable modification of such a diet may be necessary, but it is quite impossible to say how the patient will respond until treatment with insulin is actually carried out.

For making up a diet the following tables may be used. It is advisable in each case to include some green vegetables in the daily menu, though large amounts of these are frequently quite unnecessary. The following vegetables, referred to later as "Group A," may be used either singly or in any combination. Of these, each ounce contains 1 g. carbohydrate.

GROUP A.—VEGETABLES.

(1 oz. = 1 g. carbohydrate.)

Cabbage.
Spinach.
Rhubarb.
Seakale.
Grape fruit.
Cauliflower.
Cucumber.
Celery.
Radishes.
Endive.
Brussels sprouts.
Asparagus.
Mushrooms.
Watercress.
French beans.
Lettuce.
Marrow.
Tomatoes.
Leeks.

The following table shows the approximate content in grammes of protein, fat, and carbohydrate in 1 oz. of foods. It contains practically all the foodstuffs necessary for the treatment of diabetic cases.

Table of Food Values.

—	Carbohydrate.	Protein.	Fat.	Calories.
Almonds	4	5	14	168
Bread (brown)	13	1·2	0	65
,, (white)	15	2	0	75
Brazil nuts	2	5	19	204
Butter	0	0	23	212
Broth	0	1	0	5
Bacon	0	3	18	180
Cream (thin)	1	1	6	65
,, (thick)	1	1	20	190
Chicken	0	6	1	34
Cheese	0	8	10	130
One egg	0	6	6	80
Fish (white)	0	5	0	20
Meat (lean)	0	6	3	51
Milk	1·5	1	1	19
Margarine	0	0	23	212
Oatmeal	18	4	2	112
Potatoes	6	0·5	0	30
Shredded wheat	21	3	0	103
Three oysters	2	3	0	25

The following is an example of a diet which I frequently use :—

Diet for Patient Weighing about 140 lb.

	Carbohydrate.	Fat.	Protein.	Calories.
Breakfast, 9.30 A.M.				
2 oz. bacon 1 egg 1 oz. white bread ½ oz. butter ½ oz. cream 4 oz. vegetables (Group A)	20	63	15	733
Lunch, 1 P.M.				
Beef tea 4 oz. white fish ½ oz. Callard's starch-free bread ½ oz. butter ½ oz. cheese 1 oz. cream 2 oz. vegetables	3	22	35	350
Tea, 4 P.M.				
Tea ½ oz. thin cream 1 Kalari or bran biscuit (Callard) ½ oz. butter	—	15	7	160
Dinner, 6.30 P.M.				
Clear soup 4 oz. meat 1 oz. bread ½ oz. cream ½ oz. cheese ½ oz. butter 4 oz. vegetables Coffee	25	40	30	590
	48	140	87	1833

Having put the patient on a definite diet, it is best to keep him in bed for a few days at the beginning of treatment, or at any rate, he should remain indoors. His urine is collected and examined each day for sugar and ketone bodies, a quantitative estimation of the sugar being carried out if possible. He is warned to be on the lookout for any indications of hypoglycæmia, and told to take some barley-sugar if symptoms should come on. A supply of barley-sugar should always be kept in his immediate vicinity so that it may be available at any moment. Injections of insulin are then begun, and with the patient taking the same diet day after day, the amount of insulin is slowly increased until the urine becomes free from sugar, or until the dose given is a comparatively large one. On the whole, it is safer not to give more than 50 units of insulin per day as a maximum, and, if possible, a smaller dose should be employed. The principle of the treatment is to begin with small doses, and to increase the amount gradually until the glycosuria disappears, or until a dose is reached beyond which the medical attendant does not wish to go. This ensures that if symptoms do supervene, they are never severe, for under these conditions it is obviously impossible to give a dose at any one time that is much in excess of the patient's requirements. The insulin is given twice a day by injection, about 30 minutes before the morning and evening meals. Sometimes more frequent injections are done, but, generally speaking, this is inconvenient for all concerned. In bad cases it is generally quite safe to start with 10 units twice a day, but to be on the safe side, 5 units had better be used to begin with unless it is quite certain that the patient is really suffering from a severe condition. As long as glycosuria persists, gradually increasing doses as indicated below may be given.

Insulin Dose in Units.

Day.	Morning.	Evening.
1st	5	5
2nd	5	5
3rd	10	5
4th	10	5
5th	10	10
6th	10	10
7th	10	10
8th	15	10
9th	15	10
10th	15	15
11th	15	15
12th	15	15
13th	20	15
14th	20	20
15th	20	20
16th	25	20
17th	25	20
18th	25	25
19th	30	25
20th	30	30

If, after 30 units are given twice daily for a few days, glycosuria still persists, it is best to continue for a little time with this dose, and to cut down gradually the carbohydrate of the diet. In some severe cases it may be necessary to eliminate carbohydrate altogether, but in others a partial reduction will frequently result in stopping the glycosuria, and when this happens the dose of insulin may be very gradually reduced, or a little more carbohydrate may be cautiously added to the diet. By one means or another it will generally be found possible to keep a patient free from glycosuria and marked ketosis, and yet prevent the onset of symptoms. If, however, hypoglycæmic symptoms should supervene they are always mild, since it is impossible if this method is followed to give anything beyond a very slight excess of insulin in the case of any particular patient. Indeed, the onset of slight hypoglycæmic phenomena is often helpful in treatment, as an indication that the insulin dose should be very slightly reduced or the carbohydrate of the diet slightly increased. The majority of my patients remain in good health and without glycosuria on a dose of from 10 to 25 units of insulin twice a day; for various reasons it is preferable not to increase this dose too much, though sometimes it may be necessary to do so. Frequently, however, the urine becomes sugar-free long before a large dose is reached. When this happens it is best to continue with the dose of insulin that was being used when the glycosuria disappeared or to reduce this dose to a very slight extent. If sugar now appears in the urine it is obvious that the amount of insulin given is just on the low side, and a slight increase should be made. It is all a matter of common sense in adjusting diet and insulin, and obviously, when there is any tendency to hypoglycæmic symptoms, they can be removed either by reducing the amount of insulin or by increasing the carbohydrate of the diet. The one important point is not to hurry too much at the beginning of treatment, but to give progressively increasing doses of insulin spread over a fairly long period. When this is done, and the above general directions are followed, there is no danger in the use of the remedy. In certain circumstances blood-sugar estimations are useful, but it is quite possible to treat a case quite successfully without a single blood-sugar estimation. When, during treatment, the total sugar in the urine begins to decrease very appreciably, and only a small amount is present, it is best to get the patient to pass urine before each injection and to examine this specimen for sugar before giving the insulin. If at any time such a specimen of urine is found to be sugar-free, it is advisable to feel one's way carefully, so to speak, and to give a slightly smaller dose of insulin for a few times afterwards. If no symptoms appear the dose may be cautiously increased over and above the amount just necessary to keep the urine sugar-free. This will ensure that the blood-sugar is reduced nearer to the normal level. Various modifications of the above scheme may be used, but the principle on which it is based should be followed, as this gives the best protection against untoward results.

Insulin in Diabetic Coma.

In coma large doses of insulin may be given. Treatment should be begun with an injection of 20 to 25 units followed by a similar amount in two hours or less if no definite improvement takes place. In this condition blood-sugar estimations are of great value in indicating the effect of the insulin. Sugar ought not to be given along with insulin, for though this does no harm in certain cases, I have seen one patient in whom it seemed to neutralise the action of insulin. Generally, in cases of diabetic coma, insulin acts in a dramatic manner, but we cannot always be certain of success even when insulin is employed. On the whole, there does not appear to be any reason why insulin should not be successfully used in general practice.

Clinical and Laboratory Notes.

TRAUMATIC RUPTURE OF A HYDRONEPHROSIS.

BY JAS. B. MACALPINE, F.R.C.S. ENG.,
HONORARY SURGEON AND SURGEON IN CHARGE OF GENITO-URINARY DEPARTMENT, SALFORD ROYAL HOSPITAL, ETC.

IN THE LANCET of August 4th, 1923, Mr. H. W. L. Molesworth records a case of traumatic rupture of a hydronephrosis, which had occurred in his practice; he also supplied notes of 11 previously reported cases, which, with two exceptions emanating from America, were all reported in continental journals; he says that he knows of no English case or specimen which illustrates this rare accident. In view of this statement, the following report may be of interest:—

J. H., male aged 7, was admitted to my service at the Salford Royal Hospital on July 27th, 1920. The previous evening he had been jumping over a gate, when he fell and injured his left side just below the costal margin. During the night he vomited several times, and again on the day of admission to the hospital. The pain in his side had prevented sleep during the night. A doctor saw him on the 27th, about 2 P.M., and sent him into hospital. On admission the pulse was 140, temperature 99° F. The complexion was rosy and tongue clean and moist; the bowels had not acted for a period of two days; the abdomen was slightly distended and some rigidity of the muscles of the left side of the abdominal wall was observed. This was not marked and could be overcome if his attention was distracted; there was tenderness in the same region. On percussion dullness was found in the left flank, which persisted when his position was changed. The urine contained no trace of blood. My colleague, Mr. G. Jefferson, F.R.C.S., kindly undertook the operation in my absence.

Operation.—Laparotomy, through the left rectus incision; the stomach, intestines, and spleen were all found to be normal; there was no blood in the peritoneal cavity. On the left side the descending colon was set up on a ridge, and there was some free fluid (? urine) present in this region. The wound was closed. The patient was turned over on his side, and approach obtained to the left kidney through an oblique lumbar incision. On cutting through the perinephritic fascia urine escaped to the extent of about half a pint; all the tissues in the neighbourhood of the kidney were saturated with this fluid. When the kidney was lifted into the wound, it was seen that a condition of hydronephrosis existed, and that there was a tear on the posterior aspect of the pelvis about two and a half inches in length. Investigation of the cause of the hydronephrosis was difficult owing to the presence of the urinary œdema in the perinephric tissues. The kidney was removed and a drainage-tube inserted.

On the 28th he was much better, though the pulse was still 136 and there was some difficulty in respiration. During the next few days the patient suffered from consolidation of both bases. He was examined at my request by Dr. G. J. Langley, in whose opinion the pneumonia was a post-anæsthetic condition rather than one due to irritation spreading through the diaphragm. (It was found that he had suffered from pneumonia in 1916, and that he had always had a cough since then.) On inquiry as to his previous urinary history, we learned that the patient has suffered from a severe degree of nocturnal enuresis, the bed being wet each night during his sleep. He had also been sent home from school frequently, because his clothes had been wet. No other history of urinary trouble was obtainable. He had never complained of any pain in his loin. He made a complete recovery and left the hospital in three weeks.

I have recently attempted to communicate with his parents to find out if the enuresis had been affected by the removal of the kidney, but have been unable to trace the patient.

A CONGENITAL TUMOUR OF THE TIBIA.

BY D. DENHAM PINNOCK, F.R.C.S. ENG.,
ASSISTANT SURGEON, VICTORIA HOSPITAL FOR CHILDREN AND LONDON TEMPERANCE HOSPITAL.

THE following case appears to be a very rare type of congenital tumour in a bone.

A female child, 2 weeks old, was brought to the out-patient department of the Victoria Hospital, the mother having noticed a swelling on the lower part of the left leg, which she said had been present since birth.

Condition on Examination.—A smooth swelling was detected in the lower part of the left tibia, one and a half inches above the ankle, continuous with the bone. There was no redness or œdema, and the skin moved freely over the swelling. No history of trauma was obtained; the confinement had been normal, and there were no other tumours about the child, who appeared quite healthy. The Wassermann reaction was negative. X ray examination showed an intramedullary tumour in the lower fourth of the bone, causing some expansion of the bone with thinning of the shaft, and there appeared to be a certain amount of cystic change, the picture being that of a myeloma.

Operation.—On exposure of the tumour it was noted that there was none of the usual maroon colour of a myeloma to be seen. The periosteum was intact over it, but the bone was so very thinned that it could be cut with a knife, and this showed a solid tumour filling and expanding the shaft of the tibia. It was firm, white, fibrous, and striated on section, and had the appearance of a fibro-sarcoma. As the diagnosis was not certain, it was decided to remove the growth by performing a partial diaphysectomy, which was done; the specimen was sent for pathological investigation, and the report stated that the growth was a pure fibroma, showing no evidence of malignancy.

The X ray was misleading, as the tumour definitely appeared to be cystic, whereas it was a solid mass. The child is now over a year old and has developed well. Bone has been thrown out under the periosteum, but there is a gap not yet filled just about the site of the tumour, which it is hoped will be repaired completely by a bone graft. The innocent nature of the tumour seems established beyond doubt, as there are no signs of any recurrence either locally or in the form of secondary deposits.

Reviews and Notices of Books.

History of the Great War.

Medical Services: Pathology. Edited by Maj.-Gen. Sir W. G. Macpherson, K.C.M.G., C.B., LL.D., Maj.-Gen. Sir W. B. Leishman, K.C.M.G., and Col. S. L. Cummins, C.B., C.M.G., LL.D. London: H.M. Stationery Office. 1923. Pp. 600. 21*s.*

This volume embodies in some 22 chapters the sum of medical scientific research called for and stimulated by the war. At the beginning of hostilities there was little coöperation between the pathologist, the bacteriologist, and the surgeon, and so overwhelmed were the existing methods of wound treatment by the circumstances of modern warfare that, to quote Sir Alfred Keogh, "we went straight back into all the septic infections of the Middle Ages." How the pathological service was organised to meet the new conditions is set forth in the opening chapter by Sir William Leishman. About one-third of the volume deals with surgical pathology: anaerobic and non-anaerobic infections, in particular gas gangrene and tetanus. Although on a large scale these are almost exclusively war conditions, and, we trust, past history now, the knowledge acquired from 1914 onwards forms an important chapter in medical annals. Gas gangrene and tetanus are considered fully in all their aspects. A chapter on latent sepsis by Sir Kenneth Goadby discusses the pathology of wounds which after they had healed were liable to break out whether the scars were disturbed or not. In this observer's opinion it is possible by means of vaccines to keep the micro-organisms in check during any subsequent manipulative operation.

The alarming sequelæ of wound infection in the first months of the war, in spite of antiseptic treatment, called the whole principles of antiseptic treatment into question, with the result that attention was directed to the rôle played by the body tissues in combating pathogenic organisms. This new point of view is very fully expounded by Sir Almroth Wright under the title of "The Physiology of Wounds." His theories are based both on experiment and on observations made in the various zones of fighting where different conditions of surgical organisation held. He shows by experiment that the disintegrating leucocyte, by setting free trypsin, overcomes the antitryptic ("phylactic") power of the normal blood serum. In blood fluids deprived of this power ("ecphylactic") serophytic microbes can grow and multiply. By producing "kataphylaxis," whereby antitryptic serum, perpetually renewed, is transported to the foci of bacterial growth, the "ecphylactic" conditions there established are little by little abolished and the microbic growth arrested. The method of inducing "kataphylaxis" is the application of a 2½–5 per cent. solution of sodium chloride. The importance of early and careful recision and cleansing of the wound as opposed to the application of antiseptics was demonstrated by the fact that as soon as surgical hospitals were established behind the firing line and emphasis was laid on this treatment, putrid infections became rare.

The statistics of tetanus show how the mortality from this disease fell from 63·5 per cent. for the 1914 period to 37·9 per cent. in the 1916–19 period. In France and Belgium the total incidence works out at 2529 cases. The essential causal factor was proved to be the presence of tetanus spores in the soil of the battle area; outside French and Belgian territory in 1914–18 the incidence was negligible. The value of antitetanic serum in prophylaxis has now been established beyond all doubt.

The record of medicine in the war is a proud one, and perhaps the greatest of her triumphs has lain in controlling the scourge of typhoid. "Enteric fever during the war," says Sir William Leishman, "might well have been the subject of the blackest chapter in medical history." But effective measures of hygiene and prophylaxis by inoculation are a milestone in medical progress. A comparison of the annual incidence during the Great War, 2·35 per 1000, with that during the South African war, 105·00 per 1000, serves as a fitting illustration. A point of considerable scientific interest is brought forward in considering the possible protective action of typhoid vaccine against paratyphoid fevers. Statistical evidence would seem to support such protective action.

The pathology of dysentery is treated by Mr. Clifford Dobell and Colonel W. Harvey. Experience in all areas brought out the importance of accurate diagnosis from other forms of diarrhœa and enteritis, with a view to efficient treatment. Colonel J. G. Adami contributes a detailed and well-illustrated study of influenza. He summarises his data and results very concisely in three paragraphs. On the pathology of tuberculosis it is interesting to learn that the mortality rate was higher amongst men of the Labour Corps of the various countries. The statistics illustrate in a striking manner that the incidence of the disease is lower amongst the more urban and highest amongst the more isolated and scattered peoples. Chapters on Trench Fever, Spirochætal Jaundice, Acute Infective Polyneuritis, Gingivitis and Vincent's Angina, War Nephritis, and Encephalitis Lethargica complete the pathological survey. A section is also included dealing with the War Office Collection of Pathological Specimens.

A feature of several sections is the concise summary of new data. The work is fully annotated, and this, together with a complete and carefully compiled index, makes the volume one of high value to the pathologist and to the student of medical history.

Hygiene of the War. Edited by Maj.-Gen. Sir W. G. Macpherson, Col. Sir W. H. Horrocks, and Maj.-Gen. W. O. Beveridge. H.M. Stationery Office. 1923. In two volumes. Pp. 400 and 506. 21*s.* each.

In these two volumes General Macpherson and his colleagues give a complete record of the sanitary achievements of the war, of the difficulties and the dexterous methods employed to meet them. In former campaigns statistics show the balance of deaths from sickness to have been far in excess of those due to casualties. Although the increasing power of modern agents of destruction has disturbed this balance, at the beginning of the recent war disease still constituted the greatest menace to armies in the field. Moreover, as the unprecedented numbers of the troops engaged on active service greatly increased the danger, it was early recognised, in particular on the Eastern front, but hardly less on the Western, that the key to success was sanitation.

The truest estimate of the value of sanitation is given by the percentage of the permissible limit of inefficiency due to sickness in the field. This figure had been established before the war as 0·3 per cent. Any admission rate exceeding this was a danger-signal and indicated the presence of some preventable cause of disease or the onset of an epidemic. This indicator proved extremely sensitive in recording the sanitary condition of units in the field, and it is a great tribute to the thoroughness with which sanitation was carried out that the percentage for sickness, at any rate in France and Belgium, rarely reached the permissible limit. Stress is laid both in the editors' preface and throughout the volumes on the influence of the individual in maintaining the high standard of health and resulting high efficiency in the British troops. The sanitary condition of a unit is a good index of its discipline, and it was the well disciplined units in France that turned over their areas to reliefs in good sanitary order. The interest of all ranks in the paramount importance of hygiene was roused by the efforts of the numerous schools of sanitation at home and in the various theatres of war; and regulations constantly emphasised the responsibility of all units and ranks, under their respective commanding officers, with regard to measures of hygiene. Each man received definite instruction in the general principles of public health; the relation of disease to dirt, flies, and lice were kept constantly before his eyes by means of posters and pamphlets. The "sanitary conscience" which developed as a consequence became the prime factor in the prevention of wastage and in maintaining efficiency in the troops.

Major S. H. Daukes contributes a chapter on the growth and work of the schools of instruction in hygiene. This section is copiously illustrated with half-tone blocks which give a fair impression of the general appearance of essentially "home-made" field sanitary equipment, but a few more diagrammatic details might have been added with advantage. The main scope of hygiene may be summed up under four headings: water-supply, food, disposal of waste, and prevention of disease. Of these the water-supply presented by far the greatest problem, and almost half of the first volume deals with this alone. When one considers the world-wide extent of the war, and the varying geographical and climatic features of the different theatres, from the Arctic to the Tropics, the complexity of the problem is evident. The various methods of water purification are detailed at length in an appendix, with plans of the apparatus employed. The maps illustrating methods of water distribution in the East—a romance of science in itself—are on the whole poor and somewhat confusing.

The subject of rations forms one of the most interesting sections of the work. It is said, and truly, that an army fights on its stomach. So varied in requirements were the stomachs to be fed in the British troops that the task of rationing became an involved one. To take the case in East Africa, there was the problem of feeding not only the European, the Indian, and the African, but of catering for the peculiar dietaries of half-a-dozen African races, and now and again for imported labourers wholly unused to African conditions. The various dietaries employed for different races in different climes are accurately detailed, including those for prisoners of war. The economy of foodstuffs, and the increased efficiency brought about by scientific feeding and clothing, are well illustrated by the experiments carried out by Lieut.-Colonel E. P. Cathcart and Captain J. B. Orr.

More than half of Volume II. deals with the prevention of specific diseases. One section records the work done in drainage as a preventive measure in malaria, and embodies many photographs and maps. A long and detailed chapter on the prevention of infestation by lice is contributed by Colonel Sir W. H. Horrocks. Prior to 1914 it was known that lice were the vectors of typhus and relapsing fever, and during the war British and American investigators proved them to be carriers of trench fever also. In spite of all efforts to maintain personal cleanliness, lousiness constituted one of the minor horrors of the trenches. How difficult the louse was to eradicate is shown by the fact that even in the latter part of 1915 it was not uncommon to find 95 per cent. of the troops verminous after a 12 days' sojourn in the trenches.

The two volumes on Hygiene constitute a full and easily accessible record of the experience of the war. Much of the information gained is applicable only to war conditions, but the achievements with regard to water-supply and purification, the economy resulting from the increased knowledge of food values, and the control of disease by efficient sanitation, mark an advance in the civilisation of the world. Most of all one feels in reading these volumes that the awakening of the "sanitary conscience" in all who served in the forces will prove a lasting benefit to the whole human race.

Diseases of the War. Vol. II. Edited by Maj.-Gen. Sir W. G. MACPHERSON, Maj.-Gen. Sir W. P. HERRINGHAM, K.C.M.G., C.B., Col. T. R. ELLIOTT, C.B.E., D.S.O., Lt.-Col. A. BALFOUR, C.B., C.M.G. H.M. Stationery Office. 1923. Pp. 605. 25*s.*

THE second volume embodies, with the exception of three chapters, the conditions consequent on methods of warfare employed for the first time in the various fields. The major portion of the book deals with gas poisoning. The development of gas warfare, the different types of gas used, and the protective measures taken are fully considered in all their aspects. The bibliography appended to the various sections allows an estimate to be made of the work done on this subject both by the Allies and by the Central European Powers.

The results achieved in the prevention and treatment of venereal disease in the Forces during the war, and for some time subsequent to the armistice, are described by Col. L. W. Harrison. This chapter reviews all the important advances in treatment that have been made in recent years. Emphasis is laid on the preventive work done by the N.C.C.V.D. and other bodies. A consideration of the medical aspects of aviation shows that while the application of certain scientific tests to prospective air pilots was instrumental in weeding out numbers who would have proved, on the basis of past experience, unfit for war service in the air, the true criterion of fitness was the soundness of the candidate's stock, his aptitude for and prowess in games involving rapid coördination of hand and eye, and his powers of decision and judgment.

The ætiology, symptoms, and diagnosis of war neuroses and psychoneuroses (so-called "shell-shock") form an important section of the volume. Complete data of the results of treatment are not available, but in regard to the psychoneuroses the author states that "the general opinion of those who served in France was that the percentage of relapses in cases treated early and efficiently was small."

Official History of Australia in the War of 1914–1918. Vol. VII. *Sinai and Palestine.* By H. S. GULLETT. Pp. 844. 28*s.* Vol. VIII. *The Australian Flying Corps, 1914–1918.* By F. M. CUTLACK. Pp. 485. 24*s.* Sydney: Angus and Robertson. 1923.

THE purpose of this volume, says Mr. Gullett in his preface to Vol. VII., "is to record the work of the Australian Light Horse in the British campaigns in Sinai, Palestine, and Syria during the years 1916, 1917, and 1918. It is in no sense a complete narrative of those campaigns." But as he says further on, "the story in its bolder features covers the whole British force." Anyway, Mr. Gullett has succeeded in putting upon paper an account of the operations which gives the non-professional reader a life-like picture of the campaigns, of which the most striking feature, perhaps, is the heroic way in which both horses and men stood out against thirst and fatigue. The arrangements for the water-supply, which gradually got better and better, make most interesting reading. As to medical matters headquarters' handling of the transport of wounded seems to have left much to be desired. On the other side it is pleasing to note that the Turks scrupulously respected the Red Cross, and that a few days before Romani was fought a German airman dropped a message asking the Australians to mark their ambulances clearly so that they should not be bombed. This was done and subsequent bombers carefully avoided the ambulances. But the whole book is well worth reading as a record of work for the Empire which few of us have appreciated at its full value.

In Vol. VIII. the war history of the Australian Flying Corps has been mainly written from the official diaries of the four Australian flying squadrons now in the archives of the Australian War Museum, but the narrative has been largely supplemented from other sources, notably from notes written by Captain T. W. White, Lieut.-Colonel W. O. Watt, and many other officers whose names are duly acknowledged by the author. Both little air raids and the last great air battles are described, and we get a very vivid picture of what warfare in the air means, and how extraordinary are the calls which those who served in the air forces have to meet upon their courage and their resource. An interesting chapter at the end of the volume gives the story of the flights or attempted flights home to Australia undertaken by some Australian airmen.

A TEXT-BOOK OF MIDWIFERY.

For Students and Practitioners. Fourth edition. By R. W. JOHNSTONE, C.B.E., M.A., M.D., F.R.C.S.E., Lecturer on Midwifery and Gynæcology in the School of Medicine of the Royal Colleges of Edinburgh. Edinburgh: A. and C. Black, Ltd. 1923. With 263 illustrations. Pp. 508. 15*s.*

IN the fourth edition of this book a complete revision has been carried out. In the sections dealing with venereal disease the author has had the assistance of Mr. David Lees and the paragraphs on antenatal supervision have been contributed by Dr. F. J. Browne. The book is one of a handy size in which the subject is fully considered, and it is illustrated by a number of excellent drawings. It forms a good summary of the main principles of obstetric medicine as they are taught in the Edinburgh School. In discussing the structure of the corpus luteum the author inclines to the view that the cells are derived from the theca interna, but does not mention the modern theory that in reality there are two types of cells included in this structure, the one derived from the theca and the other from the granulosa cells; but, as he rightly points out, such a controversial subject can hardly be fully discussed in a text-book of this character. The account of the development of the placenta is excellent and well illustrated. An interesting description is given of twilight sleep which the author regards in certain conditions as a safe and certain method of producing amnesia with no undue risk to either the mother or the child. In view of Dr. Johnstone's practical experience his conclusions are of considerable value on this subject. The chapter dealing with the toxæmias of pregnancy, and especially the section on eclampsia, are very good and will repay reading. The author gives preference to the policy of elimination and non-interference, and in this he would have the approval of the great majority of obstetricians of experience at the present day. It is interesting to find practically no support for the practice of performing Cæsarean section in these cases. As might be expected, there is a good account of the advantages of Milne Murray's axis-traction forceps, of the instrument itself, and the best method of using it, with a number of clear illustrations. There is also a valuable table showing the advantages and disadvantages respectively of axis-traction forceps and version.

This edition can be recommended to students and practitioners as a clear and well-written guide to the practice of midwifery.

A TEXT-BOOK OF DENTAL ANATOMY AND PHYSIOLOGY.

By J. HUMPHREYS, M.D.S., F.S.A., F.L.S., and A. W. WELLINGS, M.D.S., L.D.S. London: E. Arnold and Co. 1923. Pp. 323. 16*s.*

IN the preface to this book the authors tell us that it has been written specially for the dental student. In this respect it differs from the majority of other books on this subject, which are written for the student of zoology also. Since the requirements of the former are less extensive, especially in comparative dental anatomy, there would seem to be room for such a book as this, which does not go beyond the curricula of the examining bodies in dentistry. Compared with Tomes's "Dental Anatomy," practically the only other book on this subject available for the student in this country, it is only about half the size. When one reflects that Tomes's book, for all its length, does not pretend to be an exhaustive treatise on the subject, it is obvious that the authors of this book have practised a severe compression. Indeed, we are not certain that the book is full enough even for the dental student, and we believe that the authors could have done more justice both to themselves and to their subject had the book been extended by another 50 pages. The introductory chapter to the section on comparative dental anatomy could have been lengthened with advantage.

Since comparative dental anatomy and physiology make up the expression of the principles of evolution applied to the teeth, it is necessary that the student should have a good grounding in these principles, otherwise the significance of the various changes which have occurred in the teeth and jaws will become meaningless. The student of zoology will naturally possess such knowledge before he studies comparative dental anatomy, but the dental student in most cases will make his first serious acquaintance with evolution when he commences his study of dental anatomy. For that reason we should have been glad to have seen a fuller account of Darwin's work and its later developments. The sections on the macroscopic and microscopic anatomy of the human teeth are brief, but adequate. They are not entirely free from errors. Thus the statement that the presence of the sheath of Hertwig has not been demonstrated in human teeth (p. 65) is corrected later on by an account of H. Mummery's work, which is, indeed, noted on p. 84. We regret that the authors have not included some account of L. Bolk's work on the development of the teeth. Surely the time has arrived when a frankly elementary text-book on dental anatomy should make some reference to these striking investigations. The illustrations are numerous and usually good, though some of the drawings of human teeth do not appear to be anatomically correct. The photo-micrographs are excellent, and those of Nasmyth's membrane are among the best we have ever seen.

We commend this book as a useful addition to the literature on dental anatomy.

MAN; WHAT? WHENCE? WHITHER?

By R. C. T. EVANS, M.B., B.S., M.R.C.S., L.R.C.P., D.P.H., B.Sc., F.C.S., Captain R.A.M.C. (ret.). London: Simpkin, Marshall and Co.; Chatham: Barrett and Neves, Ltd. 1922. Pp. 146. 2*s.*

EVERY thinking man has at one time or another asked himself the question of the origin of the human race and its destination. Has man arisen by the fortuitous interplay of chemical and physical forces? Is he a mere accidental product of the material world? or is he the result of the working of a superhuman intelligence?

Dr. Evans has himself felt the need for an answer to these important questions, and he has written this book in the hope that the arguments and facts which have served but to strengthen his faith may prove of equal service to others. He holds that there is indisputable evidence that there has been an evolution from the very beginning of life in this world, that this evolution has led to the formation of the highest forms of animal life, and that man himself has been derived by a slow advance from lower forms. He points out that the appearance of a mind has been a further step in the development of organic life; that consciousness is not merely an epiphenomenon, but that it is the result of an essential advance in evolution. He discusses the question of free will, and advances his reasons for thinking that its existence has resulted in the development of a class of beings who in course of time may learn always to choose the right course and reject the wrong. He deals with the question of the origin of suffering and pain, claiming that in their results they serve a valuable purpose.

The book is suggestive and will provoke thought. The questions set out in the title have been discussed with care, intelligence, and moderation.

THE LANCET.

LONDON: SATURDAY, OCTOBER 13, 1923.

THE REMUNERATION OF INSURANCE PRACTITIONERS.

THE offer of the Minister of Health in respect of the remuneration of Insurance practitioners was made in a communication to the Medical Secretary of the British Medical Association last week and appears in our columns to-day. We may assume that our readers are familiar with the offer and perhaps to such an extent with the arguments upon which it is based that little exposition is needed. These arguments are mainly statistical, paragraphs 11 to 13 of the Minister's letter giving the arithmetical justification for an offer of 8*s.* 6*d.* as the capitation fee. The Minister appeals to arithmetic in support of the usual procedure of arbitration, for more or less the mean between the opposing views of the approved societies and the panel committees, has been proposed. The 1920 award which fixed the capitation fee at 11*s.* is ignored, and the reduction of that figure two years later to 9*s.* 6*d.* is held to have inflicted no hardship upon the practitioners as shown by the fact that no resignations from the service were received on that account. We find that deduction a little specious, for surely in such circumstances only resignations en bloc can be considered as forming any practical protest. Individual members may accept a thing without liking it, and be the very persons who will resign from a service if any general movement in that direction takes place. Their inactivity does not mean acquiescence.

As was perfectly well known would be the case, the Insurance Acts Committee of the British Medical Association took little time in coming to a conclusion that the offer of the Minister of Health is unsatisfactory, and on Monday last a detailed reply to the Minister's letter was handed in. This letter will also be found in our columns, and it is such a clear and careful presentment of the reasons why the Committee cannot welcome the proposals of the Minister that any attempt to tell the message in fewer words might only obscure the points. The Committee do not consider that it is logical to compare the amount which might be paid to a general practitioner as ordinary fees by private patients with the amount which officers entrusted with the administration of medical benefit under the Insurance Acts should be paid, for the services of these officers is on a different plane, they being agents of preventive as well as of curative medicine, and members of a large scheme for the supply and collation of valuable information and for the issue of certificates. Further, the Committee challenge the statement of the Minister that the result of a capitation fee of 8*s.* 6*d.* brings the standard of living for doctors to a pre-war level, while the analogy drawn between the payment of doctors and that of the Civil Service in its higher grades is dealt with as it has been on many previous occasions. We have often pointed out that this analogy must be considered partial and misleading, if only because a doctor in general practice is on duty all day and all night and not only for certain hours, his receipts are raided by his expenses in a way which occurs to no Civil Service official, he has no pension, and no statutory holiday. The Committee, in putting forward these views, are advising the Minister of Health on the directions in which they will assist the representatives of the Panel Committees at a Conference to be held on Oct. 18th. No decision rests with the Insurance Acts Committee so that no more categorical answer than that which has been sent can be given at this stage. The views of the Committee are set out in the following recommendations :—

(*a*) That the offer of the Minister of 8*s.* for five years be definitely rejected.

(*b*) That the offer of the Minister of 8*s.* 6*d.* for three years is inadequate and that arbitration upon the lines of that of 1920 be asked for.

(*c*) That in the event of such arbitration being refused the offer of 8*s.* 6*d.* for three years be definitely rejected.

(*d*) That any agreement with the Ministry on the question of the capitation fee be subject to agreement being arrived at with regard to the special circumstances of rural practitioners.

The question whether the country is likely to get the service which has been promised to it in return for the lowest salary which arithmetic can justify is one that might well be put to the leaders of coöperative movements in any trade, in which connexion we seem to have heard such payments roundly denounced. The approved societies say that even the capitation fee of 8*s.* 6*d.* will deprive them of a surplus that they intended to use for medical purposes, a statement which does not wholly tally with the views of the Minister, who almost suggests that there will not be any surplus at all. But if these opposing views can be made to agree, and it is found that a surplus exists, who is to decide in what way it can best be used for medical benefit—the approved societies or the medical profession ? In our view this is the domain of the Ministry of Health. Increased hospital accommodation, the foundation of maternity homes—to mention two obvious needs of the country—have their claims, but improved medical service and coöperation with the preventive authorities come ahead of either. Until we have good domestic medical service we do not even know where we stand in respect of hospitals. The spirit must be protested against which leads the approved societies to constitute themselves as authorities upon the best spending of money for medical benefit. The societies cannot be the predominant partner in a partnership which does not exist. Any surplus the societies may show belongs to the public, and the right place to obtain decision as to its allocation is at the Ministry of Health.

◆

THE CASE FOR VACCINATION.

IT is difficult for a medical man to select from the mass of literature on vaccination articles, suitable for the educated layman, which set out without undue heat arguments in favour of prophylactic inoculation against small-pox and deal critically and patiently with the objections thereto. Propaganda designed to stimulate the less thoughtful section of the community is often valueless for its purpose if temperate and well-reasoned ; on the other hand, when the seasoning is applied with too heavy a hand the discriminating person turns from any dish with distaste.

A masterly presentation of the case for vaccination forms the principal feature of the October issue of *The Fight Against Disease.*[1] The article is an expanded and annotated version of an address delivered to Members of Parliament in a committee room of the House of Commons on July 25th by Dr. JOHN C. McVAIL, at the request of the Minister of Health. Dr. McVAIL submits for consideration four propositions : (1) That small-pox is worth preventing, (2) that it can be prevented by vaccination, (3) that it cannot be prevented without vaccination, and (4) that properly conducted vaccination is very safe; each proposition is dealt with in turn. First, Dr. McVail distinguishes between the mild type of small-pox, such as was seen in Gloucester this summer, and the severe type. He points out that the mild type was recognised before the days of vaccination. Jenner saw it in Gloucestershire in 1789, and it prevailed elsewhere in 1806. An eighteenth century writer declared that there was one sort of small-pox a doctor could not cure, and another which a nurse could not kill. But the severe type was probably much commoner than the mild in past centuries, and was certainly so in the nineteenth century. As regards tendency to spread, mild small-pox has two qualities, which act in opposite directions. On the one hand, it is difficult to diagnose—the symptoms are often trivial and cases may be missed; on the other, the infectivity is low because the power of infection resides in the eruption, and the less the eruption, the less is the material for conveying the disease to others. The mild type reaches Britain commonly from North America, the severe type from the East, or from North Africa, often by way of the continent of Europe, and is apt to show itself first in London. Last year's outbreak at Poplar Workhouse had a heavy fatality rate, but as it occurred within a ring fence, it could be dealt with promptly, and the disease was exterminated by vaccination and isolation. A register of births and deaths, with ages and causes, at the little town of Kilmarnock, kept between the years 1728 and 1764 by an old schoolmaster, gives some indication of the ravages caused by uncontrolled severe small-pox in the days before Jenner. During this period nine epidemics took place; for most interesting statistics Dr. McVail's paper must be consulted, but it is noteworthy that each new epidemic found its victims amongst that community in the children who had been born since the last outbreak, the older population having been protected by an attack during the previous epidemic. That small-pox is worth preventing is, indeed, hardly open to question. As to the future, Dr. McVail makes no attempt to prophesy. In England and Wales the annual notifications of small-pox fell from 289 in 1911 to 7 in 1917. Since 1917, however, the figures have mounted from 7 to 63, to 311, 280, 336, and last year to 973, while in the first half of the present year the total was 1225. No prudent man dare prophesy whether the disease in its non-fatal form will persist and breed true and remain mild, or will develop into severity and fatality. Since Dr. McVail's address was delivered a report by the U.S. Public Health Service, Washington, has come to hand calling attention to increasing virulence of small-pox in the United States. In any case, precautions should be taken. The measures worth consideration are vaccination, hospital isolation, and sanitation. Dr. McVail does not summarise the accumulated experience of 120 years, on which faith in vaccination is based, but gives briefly the nature of the evidence on which medical confidence rests, showing that if the diminution in small-pox be considered, in places and in times, side by side with the practice of vaccination and revaccination, strong proof of causal relationship appears. The larger incidence of small-pox in countries where vaccination has been neglected, the striking immunity of revaccinated small-pox nurses, the fact that, in towns where small-pox prevails, more of the unvaccinated than of the vaccinated are attacked, especially if the vaccination is recent—these and other arguments are elaborated with convincing illustrative figures. Finally, Dr. McVail points out that the whole practice of vaccination is in accordance with modern scientific knowledge of the prevention of infectious diseases. Jenner believed that cow-pox was small-pox of the cow. His belief was scouted, but is now universally accepted, and vaccine lymph may consist of small-pox cultivated on the cow and turned into cow-pox.

---

[1] Published for the Research Defence Society by Macmillan and Co. 6*d.*

As to alternative methods of prevention and control, hospital isolation alone would be useless, since every case sent into hospitals would be a centre of infection to nurses and attendants. Dr. McVail gives full recognition to the value of sanitation in respect of small-pox, but at this stage of the housing problem, at any rate, it cannot replace vaccination. The safety of properly conducted vaccination is the last proposition to be considered, and here again the writer makes no extravagant claims but almost understates the situation. Whatever the possible dangers in the past, he points out that with calf lymph there is no possibility of transmission of syphilis, because calves are not subject to that disease. As to tuberculosis, the animal from which any lymph is derived is subjected to a careful examination, the lymph being destroyed if there is the slightest cause for doubt as to its purity. The treatment of lymph in the Government Laboratories is most valuable in the elimination of pathogenic organisms. Vaccine produced in this way is as safe as science can make it. But nothing is absolutely safe; a scratch of a pin may open the door to erysipelas or lockjaw. The bite of an insect may be fatal, and the vaccine vesicle on the arm may become infected, as may any other wound. Such accidents, while extremely rare, are still deplorable, and it is difficult to see how they can be altogether avoided, though it is obviously of the utmost importance that every effort be made to prevent any kind of mismanagement of the vaccination vesicle. A paragraph on the Vaccination Acts concludes this admirable survey of vaccination. Dr. McVail shows no lack of sympathy with the sincere objector, nor does he advocate compulsion. He pleads only for the exercise by Parliament of some degree of pressure in support of its belief in vaccination, not by attempts at compulsion, which would do far more harm than good, but by drawing some practical distinction between a parent no doubt wrong-headed yet sincere in his conviction that vaccination is evil, and another parent who is merely indifferent or neglectful.

◆

WATER INTOXICATION.

The water-intake of normal man is controlled by the sensations of thirst and of satiety, and the latter, though coming less noticeably into consciousness than the former, appears to protect against too great an intake, as does the former against depletion. In addition to these psychic mechanisms of protection there are at least two others which prevent dangerous excess. The excretory power of the normal kidney has a relatively enormous range, as is illustrated by the experiment of J. G. Priestley,[1] who was able to drink 5½ litres of fluid within six hours and passed 5460 c.cm. of urine during the same period. A further protective influence in man is exerted by the stomach, which holds up any great excess of ingested water and, by causing vomiting, prevents further intake. On the pathological side an enormous capacity to drink water is exhibited by patients with diabetes insipidus, the most notable example being one recorded by Trousseau,[2] in which the patient drank 40 litres of water per diem. It is well known that in these cases the urinary output is more than equal to the intake, and there is probably a depletion rather than an excess of water as far as the bodily tissues are concerned. If, however, steps are taken to prevent the diuresis in these cases, serious symptoms may arise. LARSON, WEIR, and ROWNTREE have recorded[3] the occurrence of such symptoms—headache, nausea, asthenia, and incoördination of movement—in three cases of diabetes insipidus in which the diuresis had been checked by the administration of pituitary extract without the patients having diminished their water-intake. Similar effects were produced in normal dogs by the administration of pituitary extract, and, believing the results to be due to water intoxication rather than to the drug, L. G. ROWNTREE[4] has now performed an extensive series of control experiments.

---

[1] J. G. Priestley: Jour. of Physiol., i., 304, 1916.

[2] A. Trousseau: Lectures on Clin. Med., London, 1867.

Water in excessive amounts was administered through stomach-tubes to dogs, cats, and rabbits. In all these animals the symptoms produced were very striking. Retching and vomiting were followed by violent convulsions, similar to those produced by strychnine poisoning. These convulsions tended to recur at intervals of a few minutes, the animals in the interval being in a state of asthenia often bordering on coma. Death in coma, or during a convulsion, frequently occurred, but if recovery took place the animal was usually normal in a few hours after the cessation of water administration. In rabbits and guinea-pigs little actual vomiting occurred and the onset of convulsions was more rapid than in dogs, in whom there was frequent vomiting and sometimes diarrhœa. In rabbits it was possible to produce a condition of subacute intoxication by administering water in amounts equal to one-fourth of the body-weight daily over a long period. Careful post-mortem examination of these animals disclosed very little anatomical change in the tissues, the liver and kidneys showed a moist surface on section, but little cellular change could be made out on microscopic examination. Œdema could be seen in three situations, in the connective tissue of the renal cortex, in the distribution of the portal vein, and around the vessels of the brain. Careful control experiments seem to show that the symptoms could not be accounted for by the passage of the stomach-tube nor by gastric distension. The rapid absorption of digestive products or enzymes was also considered and negatived, and similar experiments on dogs with Eck's fistula led to the same effects which appears to eliminate any explanation on the grounds of hepatic œdema. It is noteworthy that the symptoms could not be reproduced either by rectal or intravenous administration, though the occurrence of hæmolysis made the latter series of experiments difficult to interpret. Actual measurement of the intracranial pressure showed that a definite rise occurs, and the intravenous administration of hypertonic salt solutions was effective in preventing the symptoms in subsequent experiments. From this ROWNTREE concludes that the main effects of water intoxication are due to the increased intracerebral pressure which occurs when the water-intake largely exceeds the output.

This striking series of observations must revive interest in the possibility that water intoxication alone may account for many of the phenomena of uræmia. Retention of urea, of uric acid, of creatinin, and of unknown toxic nitrogenous substances have successively been accused as responsible. More recently O. L. V. DE WESSELOW,[5] in this journal, has called attention to the inorganic phosphorous content of the plasma in nephritis, showing that an increased concentration of phosphates in the blood is of perhaps greater prognostic importance even than nitrogen retention. It is to be hoped that in future work ROWNTREE will be able to throw further light on the relation of water intoxication to these problems, which are of the greatest interest both to clinicians and to chemical pathologists.

Annotations.

"Ne quid nimis."

A HOPEFUL OUTLOOK IN MEDICINE AND DENTISTRY.

THE opening address to students of the Royal Dental Hospital, London, was delivered on Oct. 1st by Dr. Addison, whose message was the need of preserving a sense of proportion in the medical outlook. Professional problems must be approached from a public point of view; it was essential, he said, for the doctor or dentist to see things as the ordinary man sees them. He referred to two outstanding needs of our time as, first, the need of more knowledge, and second, economy—the need of getting our money's worth. Scientific research was a paying proposition, though this was not always recognised. Money spent on research brought back huge profits, not only in the saving of life but financially as well. In speaking of the means of spreading knowledge, Dr. Addison paid a tribute to THE LANCET; it was impossible to calculate, he said, the work done by such a journal, distilling every week fresh knowledge from many sources, and keeping doctors abreast of what was being done in all parts of the world for the advancement of medical science. Dr. Addison referred to the Dentists Act of 1921 in hopeful terms, since it could not fail to raise the status of that branch of the profession of healing.

Dr. William Hunter's address to the students of Charing Cross Hospital when distributing the prizes was no less optimistic. He maintained that there was much romance to be found in our profession if the student looked out for it. The amount of knowledge which the student was required to imbibe, and periodically disgorge to the examiners, was indeed stupendous; teachers to right, left, and in front of him volleyed and thundered out knowledge, sometimes regardless of the insoluble problem of how to get a quart of fluid into a pint pot. Yet still the day contained no more than 24 hours. Fortunately, however, the student maintained a sense of humour, which even the enthusiasm of his teachers could not altogether damp; and the constant contact with human beings, and the interest of the combat with disease, made life in the medical profession one great adventure. Dr. Hunter proceeded to sketch the different eras in the advances of medical knowledge, making special reference to the importance, in medicine as well as surgery, of sepsis, and the recent beneficial results in mental disease arising from careful attention to septic foci. There should be no attempt, he said, to separate the different departments of medical research and knowledge, and the clinical aspect should have first place. The profession was a hard one, the emoluments, except to a few, and those chiefly in the surgical branch, were not great; but it carried with it a human interest which nothing else approached, a high purpose, and possibilities of adding to the happiness of millions of people.

VACCINES IN CHRONIC OSTEOMYELITIS.

IN a paper[1] read in Stockholm at the fourteenth meeting of the Nordisk Kirurgisk Forening, Prof. T. Rovsing, of Copenhagen, gave a laudatory account of the action of autogenous vaccines in cases of chronic or relapsing osteomyelitis. In the acute stage of this disease he is doubtful as to the efficacy of vaccines, but in the chronic stage they frequently act like a charm. Since 1915 he has treated 23 cases of chronic osteomyelitis with vaccines. In as many as 16 cases the infecting organism proved to be the *Staphylococcus aureus*. In four other cases the *Staphylococcus albus*, in two the typhoid bacillus, and in one the paratyphoid bacillus were found. In every case there was a definite reaction to the injections, which in almost every case gave a dramatically rapid turn for the better to the course of the disease. This was often the case even when the infection had lasted for a decade or two, and had been characterised by the persistence of fistulæ or by recurrent exacerbations. The prompt and complete recoveries achieved in such cases showed vaccine therapy in marked contrast to the more primitive methods of the operating surgeon. Prof. Rovsing does not, however, underrate the ancillary services that the operating surgeon may render in such cases, and he advocates the operative removal of sequestra as a preliminary to vaccine treatment. With regard to the comparative merits of autogenous and stock vaccines, he is emphatically in favour of the former, particularly when the infecting organism belongs to that large family generically referred to as the *Staphylococcus aureus*. To hope that a stock vaccine made from one member of this group will be beneficial in a given case of *Staphylococcus aureus* infection is, in his opinion, to show a sublimely foolish belief in the patient's luck against heavy odds. But he admits there are cases in which the surgeon must suppress his contempt for the second best and give a stock vaccine. All the three cases of osteomyelitis belonging to the typhoid group responded satisfactorily to vaccine treatment, and the success in one was remarkable as the patient, aged 44, had suffered from osteomyelitis of the radius since the age of 22. Prof. Rovsing gives the name of a London surgeon who diagnosed the case as one of syphilis, with the result that, wherever the patient travelled, he was pursued by mercury, iodine, and salvarsan. These remedies did no good, and when the Wassermann reaction was found to be negative and a history was obtained of two attacks of typhoid fever, one at the age of 13 and the other at the age of 20, the typhoid character of the infection was suspected, and an autogenous vaccine, made from the typhoid bacilli found, rapidly restored the patient to complete health, which has been maintained during the six years which have since elapsed.

EVIDENCE OF PATERNITY.

SOME observations made by the bench in disposing of an affiliation order appeal at the recently held quarter sessions for the County of Devon deserve notice. Sir Francis Newbolt, K.C., the chairman, is reported in the *Times* of Oct. 6th to have said that—

> "Since the Slingsby case and a recent case in the Divorce Court, which caused a great amount of discussion, it had become known, even to the general public, that the question of paternity might often be settled by purely scientific evidence, and although that at present was beyond the means of persons generally concerned with affiliation orders, it was a matter for careful consideration whether steps should not be taken to circulate sufficient information for ordinary medical practitioners to give evidence of certain elementary indications. In the case under consideration such evidence would have been of great value."

Any comment on these remarks must be qualified by the fact that the report from which we quote is brief. In this connexion we recently referred[1] to the Slingsby legitimation action and the divorce case of Russell *v.* Russell, and in view of the learned chairman's suggestion it may be desirable to make some further allusion to the subject. If he is referring merely to the aids which an expert might give in the detection of family likeness of feature, then no doubt it is possible to summarise and classify various points in which an external similarity may manifest itself, just as a handwriting expert may draw attention to minutiæ which judge or jury can appreciate but might not readily discover for themselves. Since, however, affiliation proceedings usually take place at a time when the infant's features are as yet immature and undeveloped a note of caution may be sounded. In the Slingsby case the boy was several years of age; his features had attained a certain fixity which facilitated the detection of resemblances, and there is no doubt that Sir Bargrave Deane, who tried the case, must have derived much advantage from the expert knowledge of the great sculptor Sir George Frampton, whose assistance was invoked. In the Russell case the baby was of more tender age, and Mr. Justice Hill was careful to warn the jury against giving too much weight to the element of physical resemblance. If, on the other hand, Sir Francis Newbolt's "elementary indications" are a reference to the scientific investigation of blood-groups, to which attention was drawn in these columns in 1922,[2] it is again necessary to say that the positive results of this attractive branch of research are, for juristic purposes, scarcely complete. We repeat this note of warning, since it would be unfortunate if it were generally supposed that formulæ can be broadcasted by the aid of which the paternity of a child can be with certitude ascribed to one man or denied to another without reservations. It would be still more unfortunate if, by a misunderstanding of Sir Francis Newbolt's briefly summarised observations, an impression arose that medical witnesses were prepared to supply the necessary evidence in these cases provided that the necessary funds are forthcoming.

THE TREATMENT OF MALARIA.

AN opportune and valuable monograph[3] recently published deals with many pressing points in the treatment of malaria in the following order: (1) The value of cinchona febrifuge; (2) the relative merits of the different alkaloids of cinchona in malaria; (3) the value of some tasteless preparations of quinine; (4), (5), and (6) intramuscular, intravenous, and rectal injections of quinine; (7) the dosage of quinine; (8) the examination of the urine during quinine treatment; (9) quinine resistance. Cinchona febrifuge is as efficient, therapeutically, as is quinine in malaria, but it is much cheaper; there are many preparations of different strengths being sold under this name. The constitution of this drug should be legally defined; that made by the Government of India contains 54·65 per cent. of the crystallisable alkaloids quinine, quinidin, cinchonine, and cinchonidine. Contrary to the views of Acton, Dr. Fletcher finds that these four crystallisable alkaloids appear to be of equal value in bringing about the disappearance of malarial parasites in doses of 10 gr. given twice daily, at which strength none of them produces toxic symptoms. The alkaloid quinoidine is much more toxic and fails to destroy malaria parasites. Dr. Fletcher has done a real service in pointing out that certain tasteless preparations of quinine—i.e., quinine alkaloid and euquinine—are effacious in the cure of malaria; while, on the other hand, quinine tannate and quinine dicarbonate are quite useless. We are in entire agreement with what he has to say regarding the intramuscular injection of quinine. Serious illness and mutilation may occur as a result, and, in some cases where this has happened, the drug could have been equally well given by the mouth. When injected into the muscles quinine is not absorbed as quickly as when taken by the mouth, neither is it more potent in preventing relapses. Quinine produces immediate necrosis of the tissue into which it is injected; the dead muscle is usually absorbed in a few weeks, but may remain as a source of danger, forming an excellent medium for the growth of bacteria which may gain access either from without or from the blood-stream. These injections, then, should be reserved for patients who are dangerously ill with malaria, or for those who are comatose, or for some reason unable to swallow. In the same way the intravenous injections of quinine should be only reserved for the most urgent cases and given by a skilled physician. As regards the rectal injections of quinine, no previous writer has ever questioned the absorption of the drug through the intestinal mucosa, but Fletcher finds quinine is too irritating for administration per rectum, and causes an actual superficial necrosis of the mucous membrane; nor was there any evidence in his series of cases that any of the drug was absorbed or appeared in the urine. Great stress is laid on the examination of the urine in all cases on quinine treatment. This should be done by means of Mayer's reagent as a routine. In this way he has shown that at least 25 per cent. of the quinine prescribed in native hospitals is not swallowed by the patients at all. He explains the discrepancy of the results obtained by various observers, as well as the so-called resistance to quinine, which was observed during the war, as being due to the non-absorption of the drug. The so-called resistance is apparent and not real, and is usually due to the quinine not being swallowed. It may be also due to the adulteration of the quinine, which takes place in India and Singapore to a very great extent. One scarcely realises here that in the East the drug is worth its weight in silver; more than once it has been found that the whole supply of the quinine mixture of a large hospital was only one-third of its prescribed strength, the drug having probably been stolen and sold elsewhere.

THE SAVILE CLUB.

THE committee of the Savile Club have published for the private use of its members a history of the club between the years 1868 and 1923, but there is, we understand, no indiscretion in making public reference to an interesting volume. The club actually reached its jubilee before the war was concluded, so that at what might have been considered the appropriate stage in its existence a summarising volume could not be issued conveniently.

A quotation from No. 34 of the *Spectator*, published on April 9th, 1711, is employed at the beginning to answer a question which is not infrequently asked, namely: What are the principal characteristics of the Savile Club? The quotation runs as follows: "The club of which I am a member is very luckily composed of such persons as are engaged in different ways of life and deputed, as it were, out of the most conspicuous classes of mankind; by this means I am furnished with the greatest variety of hints and materials, and know everything that passes in the different quarters and divisions, not only of this great city, but of the whole kingdom . . . there is no rank or degree . . . who have not their representative in this club." The principles on which the Savile was established, under the name of the New Club, were three: (1) A thorough simplicity in all arrangements; (2) the mixture of men of different professions and opinions and a careful process of election; (3) early evening meetings once or twice a week. And the close association of the club with medicine, which has always been maintained, is indicated in the earliest document in existence relating to the club. That document records an invitation from the Medical Club, at 9, Spring-gardens, London, S.W., to the Eclectic Club, suggesting the occupation of certain rooms to sub-tenants. The offer was accepted by 64 persons, who constituted the original membership of the New Club, and the pecuniary guarantors. Among these are to be found such well-known people as John Morley, Henry Sidgwick, Prof. Fleeming Jenkyn, Prof. Bonamy Price, Dr. T. Fowler, later President of Christ Church College, Oxford, W. E. Forster, the great statesman, Thomas Woolner, the sculptor, and Auberon Herbert. The direct medical connexion is indicated by the inclusion among the 64 original members of Andrew Clark, of Middlesex Hospital—a distinguished physican who suffered from bearing the same name as a better known man, Ernest Hart, and Alan Herbert, the founder of the Herbert Hospital in Paris. To Auberon Herbert, whose elder brother the fourth Lord Carnarvon was also an original member, is given the distinction of being the real founder of the New or Savile Club.

The club proved attractive to the varying order of men most indicated for membership, for the list of original elections, bringing the number up to 100, comprised Leslie Stephen, Lord Dufferin, the great ambassador; Bryce, the historian and statesman; Sant and H. W. B. Davis, typical artists of their day; Sir Samuel Baker, and Prof. R. C. Jebb. The first medical recruits were Dr. John Cavafy and Dr. P. H. Pye-Smith. In two years the club became too large for its subtenancy, while its membership was increased by such adherents as Charles Dilke, Leonard Courtney, and Mr. A. J. Balfour, and its scope enlarged by an Anglo-American movement. In 1871 a house was purchased in Savile-row, the club then adopting its present name. The influx of distinguished persons continued, as inspection of the alphabetised list of members at the end of the volume shows, and in particular the following may be mentioned: three Darwin brothers, Tyndall, Prof. Henry Jackson, Andrew Lang, Justin McCarthy, J. P. Mahaffy, Poynter, William Thomson (Lord Kelvin), Walter Besant, Robert Louis Stevenson, and Francis Balfour. The intellectual level of the club was exceedingly high, the thinking was extremely broad, and at this time a listening Savilian heard his club described as: "An awful swell club: they won't elect you unless you're an atheist or have written a book." In 1882 the pressure on the premises having again become acute, the present house in Piccadilly was bought from Lord Rosebery. Through these changes the original features of the club remained, and remain, in exposition of the club's motto—Sodalitas: Convivium. In this direction the value of the table d'hôte dinner at a moderate price was realised at the first. It was deliberately introduced by the founders of the club with the view to promoting not merely social but friendly relations between the members. No one supposed that a general dinner at a fixed time was the most convenient or most luxurious method of supplying a meal to anyone who might want it, but the table d'hôte was held to make for mutual friendship among the members which was the agreed purpose of the club. There have been times in the history of the club when the table d'hôte has come in for criticism, but no foolish reformer has here been able to make headway.

In the minds of many medical men, mention of the Savile Club calls up the most pleasant of memories. Either they are or they have been Savilians, and have made many cherished friendships within its walls. We in this office have a sad and yet sweet liaison with the club. Constantly, when a prominent member of the medical profession dies, we receive messages, for private information or for use in a biography, from correspondents whose knowledge and affectionate feelings have been based upon an intimacy gained in the Savile. The authorities of the club have done well to publish these interesting annals.

EXOPHTHALMIC GOITRE IN CHILDHOOD.

Dr. Henry Heiman,[1] of New York, who has recently observed three examples in children, aged 4, 5, and 7 years respectively, remarks that although exophthalmic goitre is rare in childhood, a large number of cases have been reported. In a series of 1512 cases of exophthalmic goitre at the Mayo Clinic there were five children, or 0·3 per cent., under 10 years of age, the youngest being 4 years old. Barret, who made the most exhaustive study of the condition in childhood in his Paris thesis of 1901, collected 39 cases in children, the youngest of whom was aged 2½ years. Sex distribution shows a definite preponderance of females, 28 of Barret's cases being girls and 11 boys. Although in Dr. Heiman's cases careful inquiry into the family histories did not reveal any hereditary tendencies, heredity has played an important part in a number of the recorded cases, as in the family reported by Dubreuil-Chambardel, in which the grandmother, mother, and two daughters all had exophthalmic goitre; and in that described by Souques and Lermoyez, in which there were seven cases. In several instances, as in those reported by Gaucher and Salin, Hazen and Rost, syphilis was thought to be the underlying factor, but in none of Dr. Heiman's cases was there any history or evidence of that disease. Of the three cardinal symptoms of exophthalmic goitre—tachycardia, exophthalmos, and enlargement of the thyroid gland—Barret states that tachycardia is the first to develop in children. The exophthalmos is usually less marked in children than in adults, though it is rarely missing. In Barret's series it was absent in only eight cases. The basal metabolism test, which is the most important diagnostic guide, was performed in Dr. Heiman's cases, and showed that the degree of severity of the symptoms and signs corresponded with the degree of elevation of the metabolism rate, the results before treatment being in the first case 12 per cent., in the second case 20 per cent., and in the third case 52 per cent. Dr. Heiman maintains that the most rational treatment of exophthalmic goitre is, first, a regimen of strict physical and psychical rest for a period of 6–10 weeks. If the patient then shows no improvement a short stage of X ray treatment should be employed. If there is then no response, thyroidectomy should be performed. Considerable improvement took place in one of Dr. Heiman's cases in which partial thyroidectomy was carried out. In the other two cases, in which rest was the only treatment, the improvement was less striking.

THE CAUSATION OF THIRST.

THE sensation of thirst, so familiar yet vague and elusive, has often aroused the curiosity of the investigator, and at least two theories are current to explain its origin. Thirst might be due primarily to loss of water from the tissues in general, the actual sensation being a secondary local reference to the pharynx; or it might be a consequence simply of loss of water from the mucosa of the mouth and pharynx, and independent of the general state of the tissues. Some well-known facts point to the one theory and some to the other. Thus, the rapidity with which thirst is quenched by drinking water or by such devices as the sucking of a lemon, or the antidipsic button used by soldiers in arid climates, both of which promote a flow of saliva, point to the local desiccation theory; so does the thirst familiar to the nervous orator, or that engendered by atropin. An experimental investigation by G. T. Pack,[1] of Yale, gives further support to this view. He sought to learn whether pilocarpine, by promoting a flow of saliva, exerted an antidipsic effect, and found that it did. Rabbits deprived of water for a sufficient period were offered water for a certain length of time and the amount consumed was noted. Similar rabbits treated with pilocarpine took much less water even in double the time; yet the general desiccation of the tissues would probably, if anything, have been greater after pilocarpine than before, on account of the flow of digestive juices.

While all these facts seems to be arrayed in favour of the local desiccation theory of the origin of thirst, there is a not inconsiderable body of evidence in favour of the general tissue-desiccation theory. For instance, thirst can be allayed or prevented by intravenous or rectal injections, or by the administration of water by a stomach tube. Again, the thirst of diabetes or of chronic polyuria is not assuaged by pilocarpine. Mere wetness or dryness of the mucosa of the mouth and pharynx is therefore not the only factor. Pack's rabbits, although they took less water in a given time with than without pilocarpine, nevertheless frequently took *some* water; thirst was reduced but not abolished. A compromise between the two views would be not unreasonable. Local drying apparently always produces thirst; local drying would obviously be greatly accelerated and would reach the sensation-point sooner if there was a generalised desiccation; sensations arise first from the pharynx because, though normally moist, its opportunities for drying are greater than in other mucous membranes, owing to its forming part of the respiratory tract, and possibly also being endowed with special end-organs sensitive to drying.

THE LISTER WARD IN THE ROYAL INFIRMARY OF GLASGOW.

CONSIDERABLE feeling has been aroused both in and beyond Glasgow by the recent decision of the managers of the Royal Infirmary to demolish the Lister Ward, the workshop in which that great surgeon evolved his antiseptic treatment of wounds. The ward forms part of the old Lister block, which was left intact in the precincts of the present Infirmary when the plans were published in 1907, and it stands some 60 feet from the new building. The entire block has been condemned, but public sentiment finds expression in a petition, already signed by large numbers among the medical profession and the laity alike, that at least the first storey—the Lister Ward—should be retained as a memorial of one to whose fame Glasgow is proud to have contributed. The reason for the managers' decision appears to be three-fold: that the ward is not suited to modern requirements of surgery, that the space occupied is essential for light and air, and that to retain the ward would affect the symmetry of the Infirmary forecourt. To these utilitarian, hygienic, and æsthetic grounds for total demolition is added the cost of reconstructing the ward when the upper storeys are removed. All four arguments are ably disposed of by Mr. James A. Morris, F.R.I.B.A., in his pamphlet entitled, "A Humble Plea for the Retention of the Famous Lister Ward in the Royal Infirmary, Glasgow."[1] On the purely technical side of these questions expert advice must prevail, but the main issue at stake in the public mind is one which has again and again been a matter of controversy in recent years, and which amounts to this: is it justifiable in present-day circumstances to sacrifice a part (however small) of a modern conception to sentiment, and to honour a great pioneer of progress by an act of conservatism? If the continued use of the ward should in any way impair any patient's chances of recovery, then to protest against its demolition would be folly; but it was those who had the most direct interest in the well-being of their patients—the medical staff of the Infirmary—who were the first to sign a petition pleading for the retention of the ward. Surely, then, even at a small financial outlay, and, it may be, at the expense of the hypersensitive æsthetic taste of a few, it is justifiable—nay more, it is a civic duty, to preserve this historic battlefield in the age-long fight against disease, as an inspiration for those who follow after.

THE LONDON SCHOOL OF DERMATOLOGY.

FOR a long time it has been realised that dermatology in London has suffered from want of concentration and combined effort. Each of the large London hospitals has its dermatological department, for which, as a rule, one physician alone is responsible. St. John's Hospital for Diseases of the Skin provides a centre where there is ample material, and where there are also considerable facilities for concerted teaching, but up till now these various interests have been working independently. During the last few months negotiations have been proceeding between the medical staff of St. John's Hospital and other

---

[1] Amer. Jour. Physiol., 1923, lxv., 346.

[1] Glasgow: Maclehose, Jackson and Co. 6*d*.

London dermatologists with a view to further developing the existing facilities at St. John's, and combining to establish a central school for the study of diseases of the skin where the teaching of clinical dermatology and cutaneous pathology could be obtained. A scheme has now been adopted which has received the unanimous approval of all those concerned, and which has been sanctioned by the board of management of St. John's Hospital. The essential points of the scheme are that to the existing staff of St. John's Hospital additional members should be appointed, both active and consulting. The consultants are Sir Malcolm Morris and Dr. James H. Stowers, while to the acting staff there have been elected Dr. Wilfrid Fox, dermatological physician to St. George's Hospital, and Dr. Henry MacCormac, dermatological physician to the Middlesex Hospital. Dr. J. M. H. MacLeod will be director of the Pathological Department, Dr. Wilfrid Fox will be responsible for the V.D. Department, and Sir Malcolm Morris and Dr. J. H. Stowers will each have a seat on the board of management.

The London School of Dermatology will have an intimate connexion with St. John's Hospital, where all the teaching will be carried out, but the management, though working in close association with the medical committee of the hospital, will actually be in the hands of a larger body, consisting of the medical staff, both consulting and active, of St. John's Hospital, together with the physicians in charge of the dermatological departments of the 12 metropolitan hospitals with undergraduate medical school attached. We wish the movement all prosperity.

THE Harveian Oration will be delivered at the Royal College of Physicians of London by Prof. E. H. Starling, C.M.G., F.R.S., next Thursday, Oct. 18th, at 4 P.M.

THE Honorary Fellowship of the American College of Surgeons is to be conferred on Sir W. I. de Courcy Wheeler, President of the Royal College of Surgeons in Ireland, who has accepted the invitation of the Regents of the College to deliver the Fellowship address at the Clinical Congress in Chicago on Oct. 26th.

A SOCIAL evening will be held at the House of the Royal Society of Medicine on Tuesday, Oct. 30th, at 8.30 P.M., when the President will present the Gold Medal of the Society to Dr. Gowland Hopkins, F.R.S., professor of biochemistry at the University of Cambridge. At 9 P.M. Prof. Hopkins will deliver an address entitled Stimulants of Growth.

The Services.

Col. C. H. Bowle-Evans, Ind. Med. Serv., is appointed Hon. Physician to The King, Ind. Mil. Forces, vice Maj.-Gen. Sir William R. Edwards, I.M.S., ret.

ROYAL ARMY MEDICAL CORPS.

The undermentioned Majs. to be Lt.-Cols: Bt. Lt.-Col. A. W. Gibson, vice Lt.-Col. R. F. Ellery, ret. pay. R. N. Hunt, vice Lt.-Col. F. J. Palmer, ret. pay.

Maj. A. C. H. Gray relinquishes the temp. rank of Lt.-Col.

TERRITORIAL ARMY.

Capts. C. H. Carlton and J. Wallace to be Majs. (prov.).

Lieut. F. G. Hobson resigns his commn. and is granted the rank of Maj.

TERRITORIAL ARMY RESERVE.

Col. Sir C. A. Ballance, having attained the age limit, is retd., and retains the rank of Col.

Maj. W. T. Blackledge, having attained the age limit, is retd. and is granted the rank of Lt.-Col., with permission to wear the prescribed uniform.

ROYAL AIR FORCE.

Flying Officer J. D. Leahy is promoted to the rank of Flight Lt.

INDIAN MEDICAL SERVICE.

A. H. Craig to be Capt.

G. H. FitzGerald to be Lt.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XL.—THE MEDICAL TREATMENT OF EARLY OR SUSPECTED DUODENAL ULCER.

THE most essential factor for success in the medical treatment of duodenal ulcer is an early diagnosis. The clinical syndrome in the majority of cases is fortunately better defined than in gastric ulcer, or in any of the other organic dyspepsias, and often justifies a positive opinion. Nevertheless, whenever possible confirmation by radiography, gastric analysis, and examination of the stools for the presence of occult blood should be obtained. Lacking these, response to appropriate treatment may itself confirm a suspicion. It must be accepted that there is no accurate correlation between the clinical and pathological duration of an ulcer. Since, however, the majority of sufferers presenting themselves for investigation in hospital or clinic have had characteristic symptoms for months rather than weeks, and often for years, it seems reasonable to suppose that recognition at an earlier stage is commonly within the bounds of possibility. The importance of early diagnosis is well borne out in a recent paper by Nielsen.[1] Regarding as "cured" those patients who had remained entirely free from gastric symptoms up to or beyond two and a half years from their discharge from hospital, he obtained the following figures in a series of 182 cases. Diagnosis was confirmed by hæmorrhage, radiographic findings, or operation.

(A) Duration of symptoms before treatment.
(B) Percentage cured.

(A)	(B)	(A)	(B)
Less than ½ a year	60	3 to 5 years	20
½ to 1 year	54·1	5 to 10 ,, ...	10·8
1 to 3 years	36·9	Over 10 ,, ...	5·3

In reviewing these figures it should be noted (1) that they include cases of gastric as well as duodenal ulcer, and that a high proportion were in "older and fairly severe cases"; and (2) that the regime, as described, was very much less strict than the regimes in vogue in this country and America, and did not include certain items which we should regard as essential. With wise selection of cases, a diagnosis within the first three months of symptoms, and a carefully planned initial regime and after-treatment, a higher recovery rate than 60 per cent. should certainly be obtained.

Selection of Cases.

Young subjects are more responsive to treatment than those in the later decades. During and after middle life medical treatment should never be instituted without a thorough investigation, for occasionally an early carcinomatous ulcer of the pylorus may simulate a duodenal ulcer. Hæmatemesis or melæna occurs in a very small proportion of cases, and the treatment of hæmorrhage will not be considered here. It should, however, almost always be medical in the first instance, and in young subjects should be medical throughout. When hæmorrhage is the first symptom the outlook is frequently favourable. The treatment outlined hereunder is such as might be prescribed for a man between the ages of 18 and 40 years, convalescent from the immediate effects of a first hæmorrhage; giving a short history of uncomplicated duodenal ulcer dyspepsia; or a longer or relapsing history lacking previous adequate treatment and radiographic evidences of gross scarring.

The Aims and Details of Medical Treatment.

These do not differ from the aims of surgery. They are: (1) To secure the optimum rest for the stomach as a whole, and for the pyloric sphincter and ulcer-bearing area in particular. (2) The inhibition or neutralisation of excessive acid secretion, with a view to minimising the "acid control" of the pylorus and giving "chemical rest" to the ulcer. (3) As a preliminary to these, the eradication of focal sepsis.

---

[1] N. Aage Nielsen: Acta Medica Scandinavica, lviii., i., 1923.

Rest and Warmth.—Gastric rest is primarily obtained by general physical rest. With lowered activity on the part of the whole body food requirements are diminished, and the peristaltic and tonic activity of the stomach, subjectively expressed by hunger and appetite, are simultaneously decreased. In a similar way warmth also discourages excessive motility. The patient should therefore be put to bed in a warm room and with warm clothing, and only allowed up for visits to bath or lavatory.

Diet.—Gastric rest is encouraged by a diet which calls for the least possible motor and secretory activity, and is not calculated to cause distension. The proteins, being the only foodstuffs undergoing an important phase of their mechanical and chemical digestion in the stomach, must as far as possible be excluded. Even to milk there is the objection that its protein element creates a specific response. Thus a pint of milk is capable of producing definitely higher curves both of free and total acidity and a more prolonged gastric phase, as determined by fractional analysis, than a pint of standard gruel.[2] In practice, however, it is so inconvenient to dispense with milk that it forms a part of all ulcer dietaries, and its fluid nature and nutritional value help to outweigh the disadvantages. The soft farinaceous foods are theoretically and practically appropriate; they do not require gastric digestion or stimulate a high acidity. Fats and oils possess the important faculty of causing some actual inhibition of acid secretion; they are also lubricant and of high calorie value.

To avoid distension of the stomach small feeds must be given. To avoid the pyloric hypertonus, which results when the stomach is empty and unopposed "acid-control" established, the feeds must be given often. Eight feeds in the day at 8 and 10 A.M., 12 noon, and 2, 4, 6, 8, and 10 P.M. is a convenient distribution, though in the Sippy and similar regimes smaller and more frequent feeds are preferred. An additional feed in a thermos flask should be handy in case the patient wakes at night. The dietary may include: Benger's food, gruel made with refined oatmeal, ground rice, semolina, arrowroot, cornflour, malted milk, cream (4 to 6 oz. daily), milk (2 to 2½ pints daily), sugar or lactose, and the juice of a sweet orange or grape-juice. In addition an occasional rusk may be given to encourage the flow of saliva, to keep the mouth clean, and to provide the pleasure of mastication. No feed should exceed half a pint in bulk, and unless the patient complains of hunger they should usually be of smaller amount—say, 6 to 8 oz. The milk can be given mainly in conjunction with the farinaceous foods; when taken alone 15 gr. of sodium citrate should be added to each feed. This regime should be followed for two weeks, and then supplemented by the addition of two eggs lightly boiled, poached, or beaten up. In the fourth or fifth week two more eggs, scrambled or boiled, thin bread-and-butter without crust, custards, fruit-jellies, Force, or Cornflakes may be added. In cases with "duodenal hurry" more frequent feeds may be necessary, but very small feeds in these cases sometimes fail to achieve relief of pain. Smoking should be prohibited. After the first fortnight there should be a gradual gain in weight, and at no point should there be appreciable loss.

Medicines.—Belladonna is probably the most useful drug in the treatment of duodenal ulcer. It should be given in 5-minim doses a quarter of an hour before every alternate feed, and may be administered in conjunction with emulsion of magnesia (B.P.C.) 1 drachm to 1½ drachms. If dryness of the mouth or visual disturbance becomes troublesome three instead of four doses in the day may be given with 2 drachms of the magnesia emulsion. The action of belladonna is antispasmodic and antisecretory. It has been shown to modify the fractional test-meal curve more efficiently than alkalies, probably by causing relaxation of the pylorus and permitting duodenal reflux. Alternating with the belladonna, and again at an interval of a quarter of an hour before feeds, one tablespoonful of the best olive oil is given. Midway between feeds, when the acidity is likely to be highest, and again at bed-time, bismuth oxycarb., gr. 15, should be taken. If night pain has been troublesome a hypodermic injection of atropine, gr. 1/100, at bed-time may also be given in the early stages. For constipation liquid paraffin is generally satisfactory, but salts or enemata may be required.

Eradication of Sepsis.—Dental or tonsillar sepsis should be radically dealt with before the intensive treatment is started, and careful attention must be paid to the hygiene of the mouth throughout. If possible radiograms of the teeth should be taken. Occasionally it may be necessary to advise removal of an infected appendix. By consultation between physician and surgeon at the time of operation the desirability of medical or surgical treatment may then be assessed after actual inspection of the ulcer.

Duration of Intensive Treatment.

This should seldom be less than six weeks and never less than a month. The treatment should in all cases continue until (1) there has been no complaint of spontaneous pain for at least three weeks; (2) all reflex signs, such as "guarding" or increased abdominal reflex on the right, and deep tenderness, have disappeared; (3) the stools are found to be free from occult blood on three occasions. The benzidin test for occult blood gives sufficiently reliable results for practical purposes.

After-treatment.

This is almost as important as the intensive phase. When possible the patient should be sent for a holiday. During this period he should follow out the same rules, but allow himself greater liberality in the amounts of food consumed, and instead of staying in bed should rest after meals for one hour. He may cut down the number of feeds to six per diem while increasing their bulk; thus by introducing an extra middle-morning feed and a bed-time feed he can conform with the ordinary meal-times of the household. Potatoes mashed with butter and puréed vegetables may be added to his diet. At the end of two weeks' holiday a little cold boiled bacon or sardines may be taken with breakfast, and steamed or boiled fish with lunch or supper. The olive oil and belladonna should be continued. For the next three months the same principles should be followed with gradually increasing variety in the meals. These should still be made up as far as possible with milk, cream, butter, fats, and farinaceous foods, but with the addition once a day of fish or fowl. After three months a return to normal life and dietary is permissible, but with the following restrictions, which should be observed rigidly for a year and as closely as possible thereafter.

Hunger must be particularly avoided, and for this purpose biscuits or milk chocolate should be carried in the pocket and a night feed provided in case of waking. Physical and mental overstress and mental activity at meal-times must be avoided so far as circumstances permit. Smoking must be moderate and only "on a full stomach." Irritating particles such as seeds, skins, nuts, and vegetable fibre must be eschewed. Condiments, meat-soups, mustard, pepper, spirits, and salted or twice-cooked meats must be avoided altogether. Meals must be taken slowly and chewed thoroughly. The dentist must be visited regularly twice a year. Fats and farinaceous foods should still be preferred, and olive oil, or in winter a cod-liver oil preparation, taken with breakfast and the evening meal.

The treatment outlined above is not intended as a "stock" treatment applicable in every case of duodenal ulcer, for in no condition is it more essential to study clinical and personal peculiarities. It is sufficiently simple to allow of its employment in the patient's own home, and without the supervision of a trained nurse.

THE FUTURE OF DRUG THERAPY.*

BY W. E. DIXON, M.D. LOND., F.R.S.,
READER IN PHARMACOLOGY AND ASSESSOR TO THE REGIUS PROFESSOR OF MEDICINE, CAMBRIDGE.

THE Pharmaceutical Society of Great Britain has done so much to advance the study of pharmacy and pharmaceutical chemistry in this country in a short period, for its charter only dates from 1843, and can look back on such a phenomenal record of progress and success entirely as the result of its own exertions without Government or outside assistance, that it is well you should recognise that your President and Council are not altogether infallible, as they have shown by doing me the honour to invite me to address you to-day, although I possess no special knowledge of the art and science of pharmacy.

Materia medica is the most ancient of all medical studies and credulity in the virtues and curative powers of drugs the most inherent of all human creeds. Medicine was once nothing but a system of recipes and rituals devised to combat the symptoms of disease. With the birth of science and more particularly with the growth of pathology some insight was obtained into the nature of disease; it was material, it caused grave bodily changes, and it caused physicians to lose hope in the efficacy of drugs. Treatment assumed an insignificant position, the old shibboleths and traditions of ages were discarded. Skoda, the founder of scientific diagnosis, who exercised wide influence in the nineteenth century, was the strongest advocate of therapeutic nihilism and carried his views to the extreme limit. The more scientific part of the medical profession slowly followed in the wake. Treatment passed out of fashion and all thought and research in medicine was centred on diagnosis and pathology. All this was perhaps to the good, the recipes and formulæ, the tradition of generations, were gradually interred, but there was nothing with which to replace them, and the public left to itself was at the mercy of "systems of treatment" and the prey of the vendors of "cure-alls."

The Science of Treatment.

The science of treatment is the newest of the biological sciences; it is dependent on chemistry, physiology, and pathology, and could only come into existence when these sciences had attained some degree of completeness. So far have the views of Skoda become a part of the past that Prof. Ehrlich, for many years the director of the Institute of Experimental Therapeutics in Frankfort, in the opening sentence of an address he gave in this country, said, "There can be no doubt that the three great fields of knowledge, pharmacology, toxicology, and therapeutics in their theoretical and practical aspects form the most important branches of medicine."

I desire to give you some reasons for believing that treatment by drugs is as yet only in its infancy, and to offer you, therefore, every encouragement in the profession you are adopting, which I believe has a bright future, and regarding it in its broadest sense unlimited possibilities. The discovery of diphtheria toxin as a curative treatment opened up a great vista of the possibilities of serum therapy in the future, but this hope has not been fulfilled, and in spite of the fact that perhaps the best brains in medicine have been engaged in this field of research for more than a quarter of a century; diphtheria antitoxin remains to-day almost unique in being the only serum of proven therapeutic value in the treatment of disease in this country. During this period pharmacy appears to me to have taken little heed of this new trend of medical thought, the search for specific sera, and her disciples have continued their labours under the old conditions. Perhaps pharmacy was right, for it is only to-day that the medical profession is beginning to awake to the fact that they have been following a side issue. One would have imagined that the great progress in surgery which was only rendered possible by understanding the use and action of drugs—I refer, of course, to anæsthetics and antiseptics—would have suggested the possibilities and future of drug therapy, but such was not the case.

Our whole outlook on treatment has been altered by recent and gradually accumulated knowledge that the animal body elaborates its own drugs, stores them generally at the seat of formation, and doles them out to the tissues to meet the needs of the animal economy. Some of these are crystalline alkaloids, like adrenalin from the suprarenal capsules, and thyroxine from the thyroid gland. Others, like insulin and pituitrin, have yet to be prepared in a pure form, but we know that the former changes glucose in some way so that its oxidation can be continued by other processes in the body, and that its absence results in an excess of sugar accumulation in the blood, a condition termed diabetes; pituitrin, I have reasons for believing, is the chemical agent in the normal woman which causes the uterus to contract. Ovarian activity excites the pituitary gland and determines the liberation of pituitrin into the circulation, and it is well recognised that its use in obstetrics has largely superseded that of ergot. I cannot offer a more convincing example of the inner meaning of drug actions. The normal functions of the body are regulated at least partly by these natural drugs, and it may be that all functionings are of this nature and the object of a nerve-supply is to localise the liberation of the drug in some definite situation. Obviously, then, animal products have assumed once again a great importance in pharmacy and pharmaceutical chemistry, such an importance indeed that some knowledge of animal anatomy and physiology is almost an essential to the educated pharmacist of to-day, and I have little doubt that before long it will form a not unimportant part of your curriculum. These examples, however, only refer to internal factors as a cause of disease; and there are few organs or tissues of which it is not possible to increase or diminish the activity by the use of drugs.

Drug Treatment in the Cure of Disease.

We may now consider how far drug treatment has advanced in the cure of disease due to the introduction into the body of some extraneous factor. In several instances, especially in the protozoa, it is possible to destroy the causal agent of a disease by drugs; the disease is cured but, curiously enough, the action is not necessarily brought about by the direct effect of the drug on the causal agent. The organic compounds of arsenic have no decided effect on the spirochætes of syphilis in the test-tube, but they destroy them in the body; emetine, an alkaloid from ipecacuanha, does not kill the amœba of tropical dysentery except in the human body. The Bayer Laboratory have lately introduced a derivative of trypan-blue which destroys trypanosomes in the body of both men and animals; what this means may not be immediately appreciated; it is nothing less than the opening up of immense tracts of tropical Africa now prohibited by sleeping sickness in man and the bite of the tsetse-fly (nagana) in animals.

It is true that chemists and pharmacologists have as yet made little progress in their attack on bacterial diseases such as tuberculosis, but the fact that one of the quinine derivatives, ethylhydrocuprein, administered to man in appropriate doses, destroys the micro-organisms causing pneumonia is a happy augury even in this field. Most of these new drugs and cures have in the past emanated from Germany, because in that country the opportunity for studying higher chemistry has been open to almost all, and Germany early recognised that new discoveries meant new industries and increased wealth; with them to foster research was a business proposition, not a charitable ideal. With us research has been left to the individual, but the Pharmaceutical Society has shown originality and done much to further investigations in its special sphere, and incidentally to raise the status of English pharmacy.

* An address delivered at the opening of the session of the School of Pharmacy on Oct. 3rd.

How Drugs Work.

I propose now to consider how these drugs which are swallowed and injected so plentifully produce an action on the body tissues. It has, for example, been imagined that they combined chemically with some constituent or complicated "side chain" in the living cell, and for 50 years chemists have been trying to change the molecule of well-known chemical substances so as to produce some required action—that is to say, that the chemical constitution of a drug determined its action in the body. It is probable that subtle energy factors binding the molecule, factors not displayed in a chemical formula, control the pharmacological action: certain it is that drug action is not determined directly by chemical combination with body constituents, but rather by delicate physical processes such as those of absorption, solution, and surface-tension. Chemists have not yet determined the requirements of the molecule even for the production of colour. On the other hand, slight alterations of a molecule already complicated and with a known pharmacological action have led to the production of many useful compounds, and not infrequently, under such special conditions, we may foresee the type of action which will accrue by such alterations. Such conditions have led to the synthesis of the new local anæsthetics, antiseptics, antipyretics, diuretics, tropeines, and many others.

I may briefly state some of the factors which chemists and pharmacologists must appreciate in seeking an explanation of drug actions. At the outset we are met by difficulties, as we know so little of what determines absorption through living membranes. Why is common salt absorbed so readily into the blood and why are Epsom salts not absorbed? It is well that they are not, for a very few grains of Epsom salt make a fatal dose. Why should iron be absorbed with such difficulty and arsenic with such ease? All these are physico-chemical problems which await solution. As the drug passes through a living membrane or cell there is for a time some difference in tension on the two sides, and this passage of the drug in itself produces an action. One of the first effects of inhaling a little chloroform is to cause the bronchiolar muscle to contract; the contraction continues until the two sides of the membrane show an equal saturation of chloroform. Similarly any passage of a foreign substance into the pericardium produces an effect on the heart, the result of the alteration in tension on the two sides of the cell membrane. A wineglassful of 30 per cent. alcohol produces an effect in five minutes which we may call exhilaration, but the effect is transient, lasting half an hour or less, and so soon as absorption is complete ceases, though the percentage of alcohol in the nerve cells does not reach its maximum till about half an hour: this effect is due to the passage of alcohol into the nerve cells, and is not a specific effect of alcohol.

Drugs may act not by any particular action on living matter, but because they collect in such quantities in living cells as to clog the working of the machine. The vast group of hypnotic drugs differing widely in their chemistry have one common factor, the power of diffusion into living cells, comparative insolubility in water, and a greater solubility in fat and fat-like compounds. Lecithin and cholesterin are the principal fat-like bodies of animal tissues, and these are present especially in nerve structures. The drug will thus pass into the nerve cells, and change the physical conditions, thus interfering with the activity of the cells. So that the most powerful hypnotics are those which combine a very slight solubility in water with a very high solubility in olive oil or "brain lipoid." It is not, however, a general rule that drugs which exert a selective action on some tissue tend to collect in that tissue: strychnine does not collect in the spinal cord nor morphine in the brain: exceptions there are, such as the members of the great group of hypnotics, and the active glucosides in foxglove leaves, which are picked up from the circulation almost entirely by the heart.

Adsorption or the concentration of soluble substances on surfaces accounts for the action of some drugs. Thus if diphtheria toxin in salt solution is filtered through bone-black the toxin becomes adsorbed to the charcoal. The toxin of the cholera vibrio is similarly adsorbed by kaolin, and as the cholera infection is confined, at least in its early stages, to the alimentary canal, it is not perhaps remarkable that we should have in this insoluble inert powder kaolin a substance which is almost a specific in the treatment of this disease.

The characteristics of old age are in many cases, if not all, the results of poisoning by the absorption of toxic substances from the alimentary canal. These poisons may be produced by the growth of micro-organisms, and it was for this reason that Metchnikoff introduced his Bulgarian bacillus, which grows freely on milk and liberates acid: this infected milk, when taken in large quantities, was supposed to liberate enough acid in the alimentary canal to destroy or limit the growth of other organisms, and so prevent the formation of toxins and the onset of old age. Disinfectants have so far been ineffectual to diminish materially the intestinal flora—they poison the body before the bacteria; it may be that more happy results will accrue by using the principle of adsorption. Surface-tension again certainly explains the action of some substances, and osmosis is the principal factor concerned in the action of the saline purgatives and diuretics. Fashions in medicine and pharmacy we have always with us—for example, the modern prevalence of vaccines and perhaps the use of metallic colloids. Colloids are still on their trial, but the metallic colloids possess some remarkable properties resembling ferments: thus metallic rhodium splits up formic acid to hydrogen and carbon dioxide, and a solution of metallic platinum containing only 1/300,000 mgm. per c.cm. splits up hydrogen peroxide into water and oxygen. How far the properties of colloids can be made use of in medicine has yet to be decided.

Conclusion.

I have endeavoured to show that the future of curative treatment lies in drugs, and that the discovery of new drugs or methods of treatment can only be attained by those who have had the requisite scientific training. You cannot all, however, become wedded to science, and many of you will no doubt become retail pharmacists, and here to be really successful something more than accurate knowledge and the art of dispensing is required. Sympathy, understanding, a knowledge of life and men are of inestimable value. Suggestion is sometimes more than half the battle in the treatment of the sick, and the patient who sees his own medicine being accurately dispensed derives comfort and benefit from the ritual of the dispensing and perhaps the cheering words of the dispenser. Some years ago the late Dr. W. H. Rivers and I performed some experiments on men, estimating the amount of work certain muscles could perform under fixed conditions, in order subsequently to determine the influence of drugs. The experiments so performed were useless, since we found that any drug greatly increased the man's work. The drug day was all-important, and work was always greater on that day; the influence of suggestion was greater than the influence of the drug.

You who are entering a new profession to-day may justly be proud of your school, with its list of eminent professors, past and present, your museums, library, and laboratories, and of the Society under whose auspices you will be educated, and which has done much to raise the status of pharmacy. The researches done in these walls have of themselves opened new chapters in chemistry and pharmacy, and the publication of the great and authoritative work, the Codex, every monograph in which constitutes an investigation in itself, is but one milestone in its history.

THE REMUNERATION OF INSURANCE PRACTITIONERS.

1. THE OFFER OF THE MINISTER OF HEALTH.

THE following letter has been received by the Medical Secretary of the British Medical Association from the First Secretary of the Ministry of Health:—

SIR,—1. The Minister of Health, having given very careful consideration to the memorandum submitted by the Insurance Acts Committee in August, and to the representations made by the deputation on the 2nd instant, and having conferred on the matter with representatives of the approved societies operating in Great Britain, is now enabled to state the conclusion he has formed as to the general capitation rate which should be prescribed for the calculation of the remuneration of insurance practitioners in England and Wales, after Dec. 31st of this year, and as to the period for which that rate should remain in force.

2. At the outset it is desired to make clear that the Minister accepts unreservedly the view of the Committee that the rewards of medical practice should be such as to attract the right type of recruit to the profession, and that the remuneration of insurance practice should not compare unfavourably with that derived from private general practice of a fairly comparable kind—it being assumed that in any such comparison with private practice due account is taken of all relevant factors including, for example, the advantages of payment at a contract rate, which obviates the risks of bad debts and relieves the practitioner of the labour and expense involved in the preparation and collection of accounts.

3. In these circumstances it is unnecessary for the purpose of this communication to enter into any detailed examination of the actuarial questions raised from the latter part of paragraph 3 of the Committee's memorandum, which would be relevant only if it were sought to justify an offer on the ground that it constituted the maximum change which the available funds would bear. Nevertheless, to avoid misconstruction, it must be stated definitely that the Minister does not accept as accurate the statements contained in that paragraph. The Committee are under a complete misapprehension in supposing that the difference between the total receipts and the total payments for benefit and administration is in any sense a "surplus." It is true that at present the contributions provide more than is necessary to meet the current charges, but the liabilities under National Health Insurance increase with the ages of the insured persons and large reserves will ultimately be required to enable the claims to be met. If these reserves are accumulating more rapidly than is necessary, a surplus will be disclosed as a result of the actuarial valuation now in progress, but it must be stated that the amount of that real surplus will be so widely different from the sum which the Committee seem to have in mind as fundamentally to effect any conclusions which might otherwise be drawn from the figures given in paragraph 3 of the Committee's memorandum.

4. In deciding as to the rate now to be offered the governing consideration with the Minister has been that it should—in the language used by the then Minister in the negotiations preceding the 1920 arbitration—represent a fair remuneration, in the circumstances of the period during which it is to be in force, for the professional work involved in giving adequate attendance and treatment to insured persons under the proposed conditions of service. The case put forward by the Committee in support of a rate of not less than 9*s.* 6*d.* and possibly as much as 10*s.* 9*d.* has been examined from this point of view.

5. With reference to paragraph 4 of the Committee's memorandum, which raises the question whether the capitation rate accepted by the profession in 1913 was or was not adequate, the Minister could not agree that any difficulty in the early years of national health insurance in obtaining the services everywhere of an adequate number of practitioners was in the main due to financial considerations. If, however, or in so far as the Committee desire to base their claim now on any alleged inadequacy in the 1913 settlement, it must be pointed out that, whatever may then have been or may still be the views of the profession, there was and is a strong body of opinion among those outside the profession most conversant with the facts that the terms conceded by the Government of the day were exceedingly favourable to the doctors.

6. The Minister agrees that in the determination of a fair capitation rate some regard must be had to the award of the arbitrators in 1920. But he cannot wholly ignore the fact that the arbitration took place at a period of optimism and inflation, when increases of remuneration were being conceded very liberally on all hands, and the consequent probability that had the arbitration been held in the different atmosphere of a year later the result might have been relatively less favourable to the profession. Moreover, a consideration had then to be taken into account to which the Insurance Acts Committee drew attention—namely, the temporary enhancement of the earning power of the medical profession on account of the shortage of doctors produced by the war. It will hardly be contended that this consideration now applies in anything like the same degree.

7. While admitting that the 1920 award must be taken as one of the factors of calculation, the Minister cannot accept the contention of the Committee that he is stopped from taking into account the reduction two years later to 9*s.* 6*d.* on the ground that the acceptance of this reduction was urged by the then Minister of Health on grounds of patriotism and national economy. The Minister fully appreciates the recognition of national necessities manifested by the profession in the spirit in which they accepted a reduction of remuneration which they may not at the time have been convinced was economically justified. But it is possible now to apply an ordinary economic criterion to that rate by ascertaining what effect, if any, the reduction in the rate in fact appears to have had on the total number of doctors accepting service. Had the new rate been appreciably below the current remuneration obtainable in private practice—i.e., had it been in any true sense inadequate—it must have failed to attract new recruits to the panel and the dissatisfaction of individuals would undoubtedly have been reflected in a progressive diminution of the total number under agreement. In fact, however, no such diminution was observed. During the last quarter of 1921, when the negotiations were in progress, the total number of practitioners under contract with committees in England remained stationary, but in the first quarter of 1922, when the reduced rate became operative, the total for England increased by no less than 128, a figure appreciably in excess of the normal quarterly addition. In Wales for this period the total remained stationary. In the 18 months from January, 1922, to July, 1923, the increase for England and Wales was 552, and as this is a net figure after making good wastage by deaths and resignations, the actual number of new entrants was considerably larger. For Scotland the number of insurance practitioners was in 1920, 1706; in 1921, 1713; in 1922, 1769; and in August, 1923, 1770. It is significant also that in the advertisements of practices for sale the size of the panel has continued to be almost invariably mentioned as an inducement to purchase.

8. Underlying the succeeding paragraphs of the Committee's case appears to be an assumption that doctors are entitled to such remuneration as will secure them against any lowering of their pre-war standard of living beyond that entailed by increased taxation. This assumption the Minister is unable to accept, and he doubts whether it is really intended, since in the opening paragraph of their memorandum the Committee recognise that the necessity for every reasonable economy, both public and private, is still evident, and state that the medical profession does not expect to escape the effects of this financial stringency. In the same and following paragraphs the Committee have also recognised, and indeed urged, the necessity of relating the remuneration offered for insurance practice to that which can be earned in private practice. But the possible earnings of the profession in private practice (as in other spheres of medical employment) must inevitably be affected by general economic causes, particularly the tendency of earnings among other professional classes which are recruited broadly from the same sections of the community. If there is a tendency for those earnings to fall to the extent of a reduction of the standard of living, the medical profession, not through any act of the Government, but through the operation of ordinary economic forces, must participate in the fall, unless collateral conditions apart from earnings happen to make recruitment for that profession less attractive than for other professions (of which there is no present indication), and this must affect consideration of the appropriate remuneration to be offered in insurance practice. Thus comparison with professional earnings in general is relevant to the present question, and the Minister is bound to take note of the fact that while some professions have been more successful than others in retaining temporary war increases, it is common knowledge that a very large section of the professional classes have as a result of the war suffered a reduction of their real income over and above that entailed by increased taxation.

9. Close comparison of the average remuneration of different professions is, however, necessarily a matter of extreme difficulty and from the nature of the case, in the Minister's opinion, the most appropriate comparison for the present purpose is with the Civil Service. In the case of professions remunerated on a scale rate fair comparison is practically impossible, since these rates represent not merely the remuneration of the principal, but an allowance for clerical and technical assistance of kinds, the cost of which has very greatly increased since the war. The extent to which post-war increases represent merely compensation

for increased working expenses cannot be ascertained, and even if there were any ascertainable relation between gross and net remuneration there is the further difficulty that these scale rates in many cases (e.g., in conveyancing or architecture) are a percentage of the total cost, which in turn has been subject to varying degrees of inflation since the war. Broadly speaking, the administrative section of the Civil Service (as distinguished from the merely clerical grades), and the higher ranks of the municipal services form the only large body of salaried professional men in whose case the ratio of post-war increase in remuneration is ascertainable with any exactness. The medical profession themselves recognised this when they based their claim in the later years of the war to a war bonus, and in 1919–20 to an increased capitation rate, largely on the war bonus which had been conceded to the Civil Service.

10. It is not suggested that a bonus based on the index figure reflects with any accuracy the incidence of the rise of prices on the expenditure of the professional classes. Without admitting the validity of Prof. Bowley's criticism of the index figure, it may be conceded that a more scientific method of adjustment would have been required if the object of the war bonus had been to place the higher ranks of the Civil Service in the same economic position—apart from the increase in taxation—as they were before the war. But the bonus was not designed to secure this, except in the case of the lower grades; and in its application to the administrative grade it represents the extent to which in the opinion of successive Governments, confirmed by Parliament, the financial exigencies of the country permitted of the effects of the rise of prices being mitigated in the case of the higher paid ranks of the public service. Whatever its theoretical defects this bonus has in fact been largely adopted by public and local authorities, as affording the most generous measure of relief consistent with the paramount obligation of national and local economy. Though insurance practitioners are not in the strict sense public servants, yet in so far as they are paid out of public or statutory funds their position is analogous to that of public servants, and the Government could not in equity to the insured persons, on whom directly or indirectly the charge for medical service falls, treat them differently, unless they were satisfied that a higher rate than such considerations, taken alone, would warrant was necessary to attract and retain general practitioners in the numbers and of the type requisite for the provision of an efficient service. On these grounds, therefore, the Minister is unable to accept the alternative basis suggested by Prof. Bowley, and he considers that the principle of the Civil Service bonus may properly be applied as affording a useful indication of the extent of the reduction in the present capitation rate which the profession may reasonably be asked to accept. Concerning, indeed, the part of the capitation rate that represents an allowance for practice expenses, which have fallen substantially as the Committee recognise, the application of the Civil Service analogy to the reduction of the practitioner's gross income is favourable to the profession.

11. In the 1920 arbitration the whole-time income of a general practitioner was taken for certain purposes of discussion at £1800 gross, and this may conveniently be taken for the present purpose. The arbitrator's award was given in March, and, on the scale of bonus, applied to Civil Service salaries for the period beginning with that month, this total remuneration corresponds to a basic salary of £1177. Since Sept. 1st, 1923, when the last adjustment of the war bonus took effect, the basic salary of £1177 has produced a total remuneration of £1411. If the 11*s.* capitation rate is reduced in the ratio of £1800 to £1411 the result is a figure of 8*s.* 7½*d.* The considerations mentioned in paragraphs 6 and 7 above suggest, however, that the more appropriate starting-point is not 11*s.* in 1920 but 9*s* 6*d.* in 1922. If an 11*s.* rate leads to an income of £1800 per annum the corresponding income on the basis of the 9*s.* 6*d.* rate is £1555. This income was produced in January, 1922, by basic Civil Service salary of £1156. This basic salary now produces an income of £1386.[*] If a capitation rate of 9*s.* 6*d.* is reduced in the ratio of £1555 to £1386 the result is a figure of 8*s.* 5½*d.*

12. An alternative method of calculation is to take the pre-war figure and adjust upwards. The actual pre-war capitation was 7*s.* plus the doctor's share of what is called the "floating sixpence." It has generally been assumed in discussing remuneration that this amount was on the average evenly divided between the chemist and the doctors, although in practice the apportionment varied considerably in different areas; and it is noted that in their memorandum the Committee take 7*s.* 3*d.* as an average pre-war figure. Assuming that the reasonable whole-time income of a general practitioner before the war was somewhere about £1200, the war bonus on the Civil Service basis would be an addition of about 18½ per cent., and on this basis the 7*s.* 3*d.* would become 8*s.* 7*d.* In considering these figures, it is to be borne in mind that the rate of bonus payable in the Civil Service for each period of six months is based on the average value of the cost of living figure for the preceding period of six months. The rates for the period from September, 1923, to February, 1924, are accordingly still affected by the higher values of the cost of living figure in March and April of the current year. It will be seen that all these bases of calculation produce converging results, which indicate that on the present level of prices there is a strong case for a substantial reduction of the present capitation rate of 9*s.* 6*d.*

13. The validity of the case put forward by the Committee—for the payment of a rate of not less than, or even more than, the 9*s.* 6*d.* at present in force—has also been tested by the second method employed in the 1920 arbitration. By reference, namely, to the number of attendances given under present-day conditions, affording an indication of the time occupied in attendance on any given number of insured persons, and thus a means of estimating the whole-time gross income to which a capitation rate may be considered roughly to correspond. A careful investigation has been made of the records of services rendered in 1922 by a number of practitioners in England and Wales selected as representatives of all types of practice, including both urban and rural, industrial and non-industrial, large practices and small. These investigations were limited to practitioners who were known to be keeping careful records, and the results covered 446 practices with aggregate total lists of 736,000 insured persons. The total number of records examined was 188,606, of which 122,931 related to men and 65,675 to women. A correction by way of addition has been made for the cards relating to persons who died after the end of the year 1922, and whose records were, therefore, not in the possession of practitioners at the time the examination was made. An addition has also been made in respect of cases of removal, since it appears that often the second doctor fails to make any record of attendances given before he receives the patient's card from the former doctor. Making a liberal allowance for these omissions the final figure shows that the average number of services rendered was slightly in excess of 3·5 per insured person. This means that a practitioner with 2000 insured persons on his list gave about 7000 services in the course of the year, which may be taken (as in the arguments before the arbitrators) as approximately 300 working days. On the average, therefore, the number of patients to be seen per working day was less than 24, and of this number at least two-thirds would attend at the surgery. In the case of men the actual ratio of visits to surgery attendances was as 98 to 227, and in the case of women the ratio was 66 to 232. If, therefore, for convenience the ratio for surgery attendances to visits is taken as being 2 to 1, it will be seen that this figure is distinctly favourable to the doctors. Thus the work entailed would be on the average about 16 surgery attendances and about eight visits per working day. Inquiry from experienced practitioners indicates that a practitioner giving this amount of attendance to insured persons would be able, without overwork, to devote at least as much time to private practice, an estimate which accords with the calculation submitted on behalf of the Government in the 1920 arbitration. Thus, assuming the private practice to be at least equally remunerative, a rate of only 9*s.*, yielding £900 per annum in respect of a list of 2000, may be taken as equivalent in the year 1922 to a whole-time gross income of £1800—the income named by the Insurance Acts Committee as offering a fair reward for the whole time of a general practitioner *in 1920*, allowing nothing for the fall in cost of living and practice expenses since that time.

14. Turning to the consideration of the allowance, if any, to be made in respect of contemplated changes in the conditions of service, the Minister appreciates the readiness which the Committee have shown in considering the suggestions which have been made by the Ministry and by the approved societies for the improvement of the service, and the value of the proposals which the profession themselves have made with the same object in view. He welcomes especially the growing recognition by the profession of the fact that the shortcomings of individual practitioners are prejudicial not only to their patients but to the efficiency of the service as a whole and to its status in the eyes of the public, and that provisions with a view to strengthening the checks on defaulters are desirable in the interest of the profession itself. The discussions of the conditions of

---

[*] It may be pointed out that, if the gross income were assumed to be derived wholly from panel practice, this figure produces substantially the amount of total net income postulated in paragraph 10 of the Committee's memorandum—viz.:—

Gross income	£1386
Deduct practice expenses (24/156) as per paragraph 7 of memorandum	213
	£1173

service in the last nine months have resulted in agreed modifications which there is every reason to anticipate will materially enhance the efficiency of the service, and the Minister acknowledges with pleasure the value of the contributions made by the profession towards this achievement. But the proposed amendments of the Medical Benefit Regulations, valuable as they are, have been mainly directed to a better and less ambiguous definition of the content of the service, rather than to its extension. As the Committee recognise in paragraph 12 of their Memorandum, the only new obligation which involves any real extension of the scope of the service is in regard to the administration of an anæsthetic or the rendering of other assistance in an operation outside the contract; and having regard to the relative infrequency of such cases under existing conditions the additional obligation thus entailed does not appear to the Minister to be such as to justify an appreciable addition on this account to the capitation fee. Nor does he find in other changes proposed such an addition on balance to the demands on a practitioner's time and work as would call for any appreciable addition to the remuneration.

15. In paragraph 13 the Committee comment on the reduction of the sickness benefit claims since the commencement of the Act, and they suggest that this is in the main attributable to the provision of medical attendance for all insured persons. The improvement in the health of the industrial classes which has followed the establishment of a system of national insurance must be a cause of deep satisfaction to all. But the Minister must in fairness point out that expenditure on sickness benefit is the resultant of a number of factors the effect of which cannot be separately estimated. Improvements in the administrative methods of approved societies and economic causes have contributed too largely to the reduction in the cost of sickness benefit to make it a safe index of national health or of the efficiency of the medical service. This is illustrated by the marked reduction during the war period which was probably due mainly to the abnormal demand for labour and can hardly have been due to the efficiency of the medical service, since the shortage of doctors made the maintenance of even a minimum service a matter of extreme difficulty. In any case, however, the point which the Committee raised is only revelant to the question of remuneration in so far as it might be shown that the reduction in the incidence of duration of sickness has been secured or accompanied by increased demands on the time and energies of the doctors. In fact, there is no indication of this, and the examination of practitioners' records, to which reference has been made in a previous paragraph, indicates that the number of services rendered is lower now than it was found to be when the inquiry was made, the results of which were utilised in connexion with the 1920 arbitration.

16. As regards the difficulties of rural practitioners in sparsely populated areas in England and Wales, the Minister has only within the last fortnight received the suggestions of the Committee, and has not been able as yet to give them the consideration which they need. The action which he may find it necessary to take to meet these difficulties will not, however, in any case effect the determination of the general capitation rate, with which this communication is concerned.

17. Reviewing as a whole the case put before him by the Insurance Acts Committee, the Minister is unable to find in it ground for any such increase as appears to be suggested of the present capitation rate. He is compelled indeed, after anxious consideration of the matter, to offer a substantially reduced rate, in order to avoid injustice to insured persons, on whom in one form or another the burden must fall if any payment were made in excess of what is reasonably necessary to secure an efficient and contented service. He fully recognises that, in the interest of insured persons, he must offer a rate bearing such a relation to the possible earnings of general practitioners as will enable insured persons to obtain, in connexion with medical benefit, the reasonably contented services of a sufficient number of practitioners, including those who by their professional efficiency and personal character especially command the confidence of the insured.

18. The main considerations by which his judgment must be influenced are, on the one hand, the weight that ought to be attached to the fall in the cost of living, and to the even greater fall in practice expenses (especially those connected with locomotion), and, on the other hand, any change in the demands on the doctor's time made by alterations in the conditions of service as well as by the number of attendances which efficient insurance practitioners have found it necessary to give in order to afford adequate medical attention to their insured patients. It has already been indicated that this second group of considerations do not, in the Minister's view, point to any addition to the rate of remuneration. So far indeed as comparative number of attendances is concerned, they might be held to justify some reduction.

19. On economic grounds, whether the circumstances of to-day be compared with those before the war or with those of 1920 or with those of 1922, the conclusion is inevitable that medical earnings must be expected to fall, without impairment to the recruitment of the profession, to a point which would in no case justify a capitation rate of more than between 8*s.* and 8*s.* 6*d.*, unless the rewards of insurance medical practice are to be deliberately placed at a higher level in comparison with those of private practice than heretofore.

20. The Minister observes that the Insurance Acts Committee, on behalf of insurance practitioners, suggest that the rate now to be fixed should operate for a period of five years, and he believes that such an arrangement would be beneficial to the service, and, therefore, very desirable in the interests of insured persons. He cannot, indeed, conceal from himself that a decision in this sense would increase his difficulty in estimating satisfactorily what is the proper rate to offer. The instability of economic conditions which has precluded his predecessors, in negotiations since the conclusion of the war, from making any long-term arrangement, intrinsically desirable as such an arrangement might otherwise appear to be, still operates, though in less degree, to make difficult any forecast of the course of prices and other relevant conditions throughout so long a period.

21. The Minister must differ from the Committee in the view they take of the probable course of prices. He cannot accept the suggestion in paragraph 11 of the Committee's Memorandum that the official index figures of the cost of living will tend to stabilise themselves at a little less than the present rate. Necessarily speculative as any assumption as to the future course of prices may be, the profession cannot reasonably expect, in the light of the experience of the last 12 or 18 months, that the probability of a further decline in prices should be wholly ignored.

22. Taking into consideration all the elements in a most complex problem, the Minister has come to the conclusion that he is justified in making to the profession an offer of 8*s.* 6*d.* per head for three years. If, however, the profession prefer a contract for five years, he is prepared to offer 8*s.* per head on such a contract.

23. The Minister would add that he has been impressed in the course of his discussions with the representatives of the profession and of the societies with the general desire for a development of the present general practitioner service into a medical service of the widest scope. With this desire he warmly sympathises, though on this occasion he has not felt able to deal with the question of development. In his judgment, however, that question is one which must be dealt with at the earliest possible moment. But consideration of it must necessarily raise the whole question of the National Health Insurance system, the financial position, the system of organisation gradually developed and the possibilities of improvement, the services provided and their cost, the case for development and the practicability of providing finance and personnel for such development. It is the intention of the Minister during the currency of the new contract to pray for the appointment of a Royal Commission to investigate these matters. It seems to the Minister that the report of such a Commission is a necessary preliminary to the framing of future policy as to the whole system, including the terms of service with the practitioner. Further, the Minister is deeply impressed with the desirability of avoiding repeated discussions of the character of those which have recently taken place in regard to the position and remuneration of the medical side of the service, as they must, in his view, militate against that mutual confidence and respect which should be the basis of the relationship between doctor and patient.

I am, Sir, your obedient servant,
W. ARTHUR ROBINSON.

The Minister of Health adds that the Secretary for Scotland as President of the Scottish Board of Health, after consultation with the appropriate Scottish bodies concerned, and after careful consideration of the position as regards Scotland, concurs in the terms of the First Secretary's letter, while matters such as mileage for Scottish doctors will be considered separately with the Insurance Acts Subcommittee (Scotland) of the British Medical Association.

2. THE REPLY OF THE INSURANCE ACTS COMMITTEE.

The following reply was sent on Monday last to the Minister of Health from the Insurance Acts Committee:

SIR,—1. The Insurance Acts Committee met on the 4th instant to consider the Minister of Health's reply to its case for the insurance capitation fee, contained in your letter of the 3rd instant. I am instructed to state that the Committee considers the reply of the Minister very unsatisfactory, not only in the offer which it finally makes, but in the manner in which that offer is attempted to be justified.

2. It appears to the Committee that, though in paragraph 2 the Minister states that he accepts unreservedly its

view that the rewards of medical practice should be such as to attract the right type of recruit to the profession and that the remuneration of insurance practice should not compare unfavourably with that derived from private general practice of a fairly comparable kind, he seems in the remainder of his reply to ignore both these aspects of this question. Instead of regarding the National Health Insurance system as a matter affecting the public health of the nation, he has apparently directed his attention mainly to the purely commercial question of what is the lowest sum for which medical attendance on insured persons can be obtained when they are ill.

3. The national aspects of the matter and the value of the practitioners' services in relation thereto are disregarded. The Committee, on the contrary, views the insurance medical service as having been set up not merely to assure medical attendance on certain wage-earners when they become ill, but to promote the national health by having regard to preventive as well as curative methods, by facilitating research into the beginnings of disease (for which such a service obviously offers unrivalled facilities) and for making such investigations and reports on health matters as the Ministry of Health might properly require. This work, even though some of it has not yet developed very far, has a bearing on the subject of remuneration; and in order that the growth of the service in these directions may be encouraged and not stopped it is necessary to attract to it and retain in it every type of practitioner from the new recruit into the profession to the experienced and successful family doctor of standing. To fix such a rate of remuneration as would tend to exclude the latter would deprive the service of very valuable members and would severely restrict that free choice of doctor by the insured population which is an essential feature of the scheme. It would militate also against that increase of numbers of insurance practitioners which alone will allow of the wide distribution of insured persons amongst doctors in such a way as to permit the best work to be done without any distinction between one class of patient and another. The Committee views with very grave concern any policy which might tend to hinder developments on these lines.

4. The Committee has no desire to ignore the relationship between the remuneration received from insurance practice and that from private fees or from contracts in which the State is not concerned as a party. Statements that such private fees yield a remuneration materially lower than that represented by the present capitation fee of 9*s*. 6*d*. will not stand investigation. There are, of course, some practices in which relatively low cash fees are accepted on account of the poverty of the people and the fact that they are without State aid. With these exceptions the Committee finds that, dealing with classes of the community from which insured persons are drawn, taking the lowest fees for each item of attendance that are accepted, ignoring such extra charges as are made for special services (e.g., night visits, fractures, minor operations, anæsthetics) included within the insurance contract, and assuming the same number of consultations and visits as occurs with insured persons, private fees work out frequently at 14*s*. 6*d*. per head, sometimes at 19*s*., and very rarely at less than 9*s*. 9*d*. Clubs are usually established because there is difficulty in paying for medical attendance at the usual private rates, and, being without State aid, are frequently accepted at rates below those of the National Health Insurance Service. Nevertheless, there are contract rates which vary from 15s. to 9*s*. 9*d*. in various parts of the country according to circumstances, and most of these are for a limited service (i.e., excluding special services such as those mentioned above), many require a health examination prior to admission as members, and some even exclude all cases of chronic illness.

5. Paragraph 2 of the Minister's reply speaks of the advantages of a contract system as obviating the risk of bad debts. The importance and extent of bad debts in connexion with private medical practice has been greatly exaggerated, mainly by representatives of approved societies in their endeavours to prove a case for a low fee. Except perhaps during the first year or two of a newly-established practice, such debts are relatively small. The report of Sir W. Plender on all kinds of practices contained in five typical towns puts them at 6½ per cent. or, including cost of collection, at 8 per cent. Relief from these is, of course, an advantage of contract work, but it must be remembered on the other hand that the great and growing body of restrictions on the independence of insurance practitioners set up by the regulations under the National Health Insurance Act, and the imposition of clerical and other duties not strictly medical, are regarded by many as far more than balancing that advantage.

6. The Committee cannot agree that anything contained in the Minister's reply affords a good reason for ignoring the claim that whatever may be regarded as the proper capitation rate should be provided as a first charge from the National Health Insurance Fund, which, as is shown by the Committee's memorandum on this subject, is well able to bear any such charge. This is not the same thing as trying to "justify an offer on the ground that it constituted the maximum charge which the available funds would bear." The Committee made no such absurd suggestion and would again refer the Minister to paragraph 3 of its memorandum and to the Committee's memorandum, drawn up on reliable expert investigation and advice, "The National Health Insurance Fund" a copy of which accompanied the Committee's case. Subject to much more detailed information than has up to now been vouchsafed to it the Committee would suggest that the statement contained in paragraph 3 of the Minister's reply—viz., "the liabilities under National Health Insurance increase with the ages of the insured persons and large reserves will ultimately be required to enable the claims to be met," requires much modification when applied to a national scheme which can depend on an unfailing supply of young lives. In view of the very inadequate way in which this part of its case has been met the Committee is not prepared to accept ex parte statements as to the possible demands on the Fund and insufficiency of the "real surplus." These the Committee finds quite unconvincing and asserts with confidence that the conclusions of the Committee's report, alluded to above, remain unshaken.

7. The Committee notes that in paragraph 6 the Minister to all intents and purposes throws over the arbitrators who accepted the thankless task of settling the fee in 1920. This is profoundly unsatisfactory to those who believe in a rational way of settling differences. It is also very ungracious to the arbitrators and to the then Minister, who, doubtless with due regard to the advice of the permanent officials, offered the same sum (11*s*.) as was afterwards confirmed by the arbitrators.

8. The suggestion is made in paragraph 7 of the Minister's reply that the reduction of 9*s*. 6*d*. in 1922 was received with equanimity by the profession, or at any rate acquiesced in without much sign of dissatisfaction, and this is supported by the statement that the number of new entrants into the insurance medical service did not fall off but even increased. The increase in the first quarter of 1922 was in all probability largely due to doctors who had left war employment and settled into general practice. But the Minister's argument entirely ignores the elementary fact that in industrial and rural areas, so long as a panel system exists, new entrants into practice *must* join it. The Committee would remark that the fact that the size of panel is almost invariably mentioned in advertisements of practices for sale as an inducement to purchase, has no such significance as that implied by the Minister. It has always been usual for men desiring to sell practices to give some indication of the amount derived from their settled appointments and contract work and there is no special or preferential goodwill attached to insurance practice.

9. The Committee takes strong exception to the statement made at the commencement of paragraph 8. At no time has the Committee, either explicitly or implicitly, asked that "doctors should be entitled to such remuneration as will secure them against any lowering of their pre-war standard beyond that entailed by increased taxation." Reference to the Committee's case (paragraph 10) will show its contention to be that even if the capitation fee were 10*s*. 9*d*. the expenditure of the insurance practitioner would have to be reduced to 16 per cent. below what Prof. Bowley argues would be proper if "the standard of living is not to be seriously lowered." If the 8*s*. 6*d*. were accepted the standard of living of the insurance practitioner would have to be reduced to 25 per cent. below the pre-war standard. It is noted that the Minister's reply declines to discuss the careful reasoning of Prof. Bowley. No reason is assigned for this reticence and the Committee will not indulge in surmise. The medical profession is quite willing now, as it always has been, to take its fair share in any sacrifices required by national circumstances, but it believes that the arguments it has put forward, supported by the analysis of Prof. Bowley, justify the profession resisting the reduction in its standard of living to the extent that the Minister is endeavouring to force upon it.

10. The Committee cannot deal with the arguments set out in paragraphs 11 and 12, because, so far as it is able to understand them, it appears as if the Minister was comparing the gross income of the medical practitioner with the net income of the civil servant. The Committee is, indeed, unable to admit the validity of the greater part of the arguments in these paragraphs at all. The £1800 that was taken as a basis for certain arguments in the 1920 arbitration was a maximum gross income and appears to be entirely out of place in the connexion in which the Ministry uses it. The only line of comparison with the civil servant which appears to be useful or, indeed, to have any relevance is that adopted in the table of Prof. Bowley's memorandum. It is here repeated with such modification as is necessary.

PROF. BOWLEY'S TABLE.

—	1914.	March.				July, 1923.*	
		1920.	1921.	1922.	1923.		
Amount	£500	£819	£905	£758	£696	£696	£684
Relative numbers	100	164	182	152	139	139	136
Amount	£1000	£1544	£1690	£1330	£1234	£1234	£1219
Relative numbers	100	154	169	133	123	123	121
Doctor's rate per patient	7/3	11/–	11/–	9/6	9/6	9/6	8/6
Relative numbers	100	152	152	131	131	131	117
Official cost of living index	100	230	241	186	176	169	173
Estimated middle-class expenditure	100	164	—	—	—	157	—

* Rates as just become operative for civil servants and proposed for doctors.

The table shows that though the doctor's relative rise of remuneration never reached the height of the civil servants, the Minister's new proposal will leave it lower. Moreover, as Prof. Bowley points out, the doctor is at a great disadvantage with the civil servant when making adjustments of his expenses and way of life. It appears also to the Committee that the civil servant's pension has been overlooked in stating the Minister's case.

11. With reference to paragraph 13 of the Minister's reply, the figures which the Committee has collected with great care show a somewhat higher number of items of service than that shown in the reply. The Committee notes, moreover, that though adjustment has been made in the Minister's figures for cases of death and removal, no adjustment has apparently been made for those who have ceased to be insured. Further, the Minister assumes that a practitioner with a list of 2000 insured persons, who, in most cases, would be practising in a poor industrial area, has not only time but also opportunity for doubling his income by private practice. It is submitted that in the case contemplated this would not be possible. A fairer instance, however, would be to take the case of a practitioner with the average list of 1000. This would produce at 8*s*. 6*d*. roughly £425 a year. As the insured population is more than one-third of the total population of Great Britain, less than two-thirds remain as the field for private work. From this two-thirds there have to be deducted, first, the day-to-day population of such institutions as workhouses, asylums, hospitals, prisons, and orphanages, together with naval and military establishments, &c.; and secondly, such medical attendance as is provided by public authorities, such as that given at infant welfare and school treatment centres. Further, in this sphere the practitioner concerned has to share the opportunities of practice with that large number of other private practitioners who are not engaged in the insurance service. The case would be more fairly stated if we allow to the average doctor with 1000 insured persons on his list an opportunity of earning a similar amount to this from private work. This brings the total income of the average insurance practitioner not to the £1800 required by the Minister's argument, but to less than half that sum.

12. The Committee thanks the Minister for his appreciation of its readiness to initiate improvements in the service and to accept suggestions for this purpose coming either from the Ministry or from the approved societies. The testimony of the Minister is all the more valuable in view of the ostentatious lack of appreciation shown by the approved societies. The Committee must point out that it did not ask for an evaluation of the additional services which will fall on practitioners under the contemplated changes in the conditions of service. It cannot, however, admit that these new services are of small value, indeed some individual practitioners, and the practitioners in some areas, will probably find the additional services rather onerous.

13. In paragraph 15 the Minister speculates as to the probable causes of the reduction of the sickness benefit claims. The Committee is quite willing to agree that many factors have combined to bring about this happy state of affairs, but no medical man who has examined this question has any doubt that one of the chief factors (and probably *the* chief factor) is the ability of a large section of the population to take advantage of medical advice at an early stage of an illness without any fear of contracting a doctor's bill. The Committee views with some alarm the hint given in paragraph 15 and the last sentence of paragraph 18 to the effect that if by improvements in medical education and skill or by the extension of the preventive side of medicine the number of individual items of service rendered could be reduced, this might be held to justify some reduction in the pay of those who were instrumental in thus conducing to the health and comfort of the insured population and the improvement in the national health. This is, indeed, a striking example of the defect in the Minister's reply to which the Committee has drawn attention in paragraph 2 of this letter.

14. The Committee is in doubt whether it understands the suggestion made in the middle of paragraph 17 of the Minister's reply, where it is suggested that unless the capitation rate is substantially reduced some injustice will be inflicted on insured persons. If this paragraph is meant to suggest that an increase on the 8*s*. 6*d*. offered would mean that the insured person must pay an increased contribution the Minister has quite misunderstood this part of the Committee's case. The Committee maintains it has established that the National Health Insurance Fund is in such a healthy condition, owing to windfalls of various kinds as well as to unexpected reductions in the cost of sickness benefit, that it can quite easily afford to pay the doctor the present capitation rate, or even more, without calling on the insured person or the employer or the State to make any increased contribution, and without depriving the insured person of any additional benefit to which he is at present entitled. It would be a poor consolation to the insured person if a discontented and therefore less satisfactory medical service was forthcoming, even though by the reduction of the capitation rate the approved societies were enabled to declare some additional benefit.

15. The delay in sending suggestions with regard to the different conditions of rural practitioners was due to the fact that the Committee is waiting for the appointment of the small joint committee suggested by Sir Arthur Robinson at the interview with him on Sept. 20th. The proposals mainly of a general character, already submitted, are, of course, subject to the opinion arrived at after the deliberations of such a joint committee, and it is hoped that there will be no further delay in proceeding with this matter. This is an essential part of any settlement.

16. The Committee desires briefly to summarise its case. It has done its best to find out the alleged defects in the National Health Insurance system, and to accept, or itself to suggest, the remedies. The National Health Insurance Fund is at present well able to provide the proper capitation fee for the standard of service required. The proper fee is to be found most simply by calculating what is the present value of the 11*s*. offered by the Ministry in 1920 and confirmed by arbitrators; so far as the Committee can ascertain, with the best expert advice at its disposal, that sum is somewhere between 10*s*. 4*d*. and 10*s*. 9*d*. The Committee was willing to be convinced that its calculations were wrong if this could be demonstrated, but the Minister's reply has not shown the Committee that its calculations were wrong. Nevertheless, though convinced that the fee mentioned above is an equitable one, the Committee has indicated that in view of all circumstances the essential point is that there is no justification for reducing the present amount of 9*s*. 6*d*.

17. As the Committee informed the Minister at its interview on the 2nd instant, its duty is to report to the Local Medical and Panel Committees, which will instruct representatives who will attend at a conference on the 18th instant. The decision as to the acceptance of the Minister's offer rests in the hands of that conference but the Committee has had no hesitation in making the following recommendations:—

(*a*) That the offer of the Minister of 8*s*. for five years be definitely rejected.

(*b*) That the offer of the Minister of 8*s*. 6*d*. for three years is inadequate and that arbitration upon the lines of that of 1920 be asked for.

(*c*) That in the event of such arbitration being refused, the offer of 8*s*. 6*d*. for three years be definitely rejected.

(*d*) That any agreement with the Ministry on the question of the capitation fee be subject to agreement being arrived at with regard to the special circumstances of rural practitioners.

If the Minister is able to express any definite views as to the propriety of arbitration on the lines indicated, it would be of the greatest value and convenience if the Committee could be put into possession of these prior to the meeting of the conference.

18. During the whole of this year with a view to the present negotiations the Committee has been striving for a settlement by consent and for the cultivation of friendly relationship with representatives of approved societies and others interested in insurance administration. It sincerely believes the service needs a period of tranquillity in order that it may have a chance to develop. But the Committee feels that that period of tranquillity is not likely to be gained by the acceptance of an offer which insurance practitioners will regard as inadquate both in itself on economic grounds and as tending to hinder the progressive usefulness of the service to the nation. The Committee fully recognises the very difficult nature of the decision which the Minister is called upon to make and his evident desire to act fairly and impartially.

19. The Committee would very seriously direct the Minister's attention to what will undoubtedly be the effect produced on the average insurance practitioner's mind by the reduction now proposed. Knowing as he does the immense amount of time and trouble his representatives have taken to find out the defects in the system and remedy them, and to suggest ways and means whereby the service may become one of which the nation and the medical profession may feel proud, the practitioner will be struck with the fact that the net result of it all is a proposed reduction in a fee which has already been reduced, without any expert inquiry, by 1*s.* 6*d.* per head per annum from the 11*s.* allowed by arbitration. He will also note that the reduction has been brought about largely at the instigation of the approved societies, who, because they are the agents of the State through whom sickness and maternity and certain additional benefits are paid, claim a deciding voice in the determination of what the medical profession should be paid for their part in what is supposed to be a national service. The result of his examination of the position will be discouraging. He is not likely to be at all hopeful of the service ever becoming a really national one untrammelled by associations with bodies whose interests it is only too plain are concerned much more with the building up of surpluses than with the building up of a satisfactory National Health Insurance scheme which shall be preventive as well as curative.

20. The Committee entirely shares the view of the Minister that repeated discussions of the kind which have recently taken place are not in the interest of the medical profession, the public, or the National Health Insurance system, and it would make many sacrifices to avoid such discussions. It therefore welcomes the statement of the Minister that at an early date the whole question of the National Health Insurance system must be inquired into. Such an inquiry would, however, be likely to have an outcome much more useful to the country if it were set up after a period of several years during which the system had worked smoothly and without interruptions caused by war, immediate post-war conditions, or disputes as to remuneration, and the Committee hopes that the Minister may even yet be able to make an offer which the Committee could recommend for acceptance to its constituents. The Committee has every wish to help towards a peaceful solution.

I am, Sir, your obedient servant,

ALFRED COX,
Medical Secretary.

The representatives of the Local Medical and Panel Committees will have, therefore, before them at the conference to be held on Oct. 18th the important issues in a concrete form.

ST. MARY'S HOSPITAL MEDICAL SCHOOL: POST-GRADUATE COURSE.

(*Concluded from p. 806.*)

ON Oct. 1st, at 11 A.M., Mr. ALECK BOURNE discussed in a paper, which was illustrated by lantern slides, the

Anticipation of Mechanical Difficulties in Labour.

He stated that his findings were deduced from the study of the records of over 2000 labours in Queen Charlotte's Hospital. He believed 90 per cent. of stillborn births to be due to instrumental delivery, and he hoped that by careful antenatal diagnosis this percentage would be largely reduced. Neglecting fœtal causes and dealing only with the maternal aspect, he advised three main methods for the detection of probable mechanical difficulties: (1) The taking of a careful obstetric history; (2) measurement of the pelvis; (3) estimation of relation of head to brim at the thirty-sixth week. He laid stress on the tendency of the weight of the fœtus to increase in multiparæ shown by the necessity for craniotomy in the later pregnancies of some women whose previous children had been delivered by means of forceps. He urged that even apparently normal measurements could prove fallacious, and showed slides of generally contracted pelves, and those which were generally contracted and also flat, where apparently normal measurements were present. He considered the posterior interspinous diameter to be valuable, since it gives an indication of the measurement of the basin of the pelvis proper, and showed tables demonstrating the possibility of error resulting from reliance on measurements alone. As to the relation of head to brim at the thirty-sixth week, if (*a*) the head was engaged, it would always go through; if (*b*) the head was engaging, Mr. Bourne advocated firm pressure from the shoulders for 10 seconds or more to convert (*b*) into (*a*). With fat or intolerant patients an anæsthetic might be necessary. If (*c*) the head was floating above the brim, it would usually be extended and high up, towards the umbilicus. The treatment would be influenced by the obstetric history, but in many cases he advised induction at thirty-sixth week and close observation. If the major diameter of the head began to engage, and if overlapping began to be reduced, the patient could be left to go on with labour. If not, Cæsarean section would be indicated.

Dr. WILFRED HARRIS gave a lecture on

Encephalitis Lethargica.

After differentiating acute encephalitis and anterior poliomyelitis from encephalitis lethargica, he recalled the fact that the last-named disease was first recognised in 1917, when owing to the frequency of bulbar symptoms it was for a while confused with botulism. Attacks started with soreness of the throat and difficulty in swallowing, accompanied by bilateral ptosis, diplopia, and sluggish pupils—in fact, ophthalmoplegia, both external and internal. He emphasised that, in spite of the name "lethargica" and the sleepy appearance of the patient owing to the ptosis, one of the most troublesome symptoms of this disease was insomnia. Only in a very advanced case was coma present, and the patient usually replied to questions quite rationally though slowly. Certain authorities had estimated the mortality as high as 40 per cent., but Dr. Harris failed to agree with this view. From his own experience of over 100 cases he would have put the mortality as about 10 per cent. In the early cases there was absence of headache; the pulse-rate was not usually disturbed, but where it was raised to 120 or so the prognosis was always grave. The diagnosis was simple with bilateral ptosis present, otherwise it was easy to miss. Sluggish and perhaps unequal pupils were helpful points. The disease was often more like tuberculous meningitis than any other condition, particularly in adults. Incidentally, a common mistake was to forget that tuberculous meningitis did occur in adults of varying ages; among his own cases he had had patients up to 60 with this disease. Lumbar puncture was of no assistance, except from the point of view of eliminating other diseases; it gave little help in the differential diagnosis from tuberculous meningitis, since a lymphocytosis was common, and a leucocytosis sometimes occurred. Completely negative lumbar punctures did occur occasionally in tuberculous meningitis, which disease was invariably fatal. Relapses might occur in encephalitis lethargica, and sometimes stiffness, going on to clonic spasms of muscles, persisted for weeks or months afterwards. The typical paralysis agitans mask-like face and rigidity of limbs was one of the sequelæ which once seen was never forgotten. As a rule, there was no tremor. Whereas paralysis agitans had a hopeless prognosis, with a gradual downhill path, the prognosis of the paralysis agitans type of encephalitis lethargica was different.

Slight cases might recover completely, and more severe cases got no worse. The exception to this was in the rare instance of mask-like rigidity, &c., coming on some months after the original lesion. This was of very bad prognosis. The treatment was that of symptoms as they arose. Urotropin was given with the view that it disinfected the cerebro-spinal fluid, but it was doubtful if it affected the disease in any way. For insomnia, failing bromides, Dr. Harris used medinal in 5, 7, or 12 gr. doses daily.

Dr. E. GRAHAM LITTLE dealt with the

Diagnosis of Some Common Diseases of the Skin,

showing numerous cases. He discussed the nomenclature of skin diseases with special reference to eczema, which was really only a clinical term of convenience. Dermatologists, both here and abroad, had at intervals endeavoured to re-classify and describe skin conditions. Hence, the confusion of mind which often attended the study of manuals on this subject. He preferred the classification of eczema ("an exudation which when dry stiffens linen") into: (*a*) Eczema of external origin—e.g., from exposure to excessive cold, or various forms of heat, &c.; (*b*) eczema of internal origin arising from some constitutional cause, due to special sensitisation on the part of the individual to specific bacterial poisons. Eczematoid ringworm deserved mention; it occurred in the groins and extremities—most commonly it started in the toes and might exist there for years before spreading elsewhere. It was frequently indistinguishable from true eczema. Infantile eczema, reported by the mother as due to teething, was common in the first three months of life, and had no connexion with dentition. Its origin was rather in exposure to wind, sun, or cold, combined with dietetic errors and incessant feeding. Babies subject to this condition were generally fat and too heavily clothed. Treatment consisted in restriction of starches, in regular meals, and fewer clothes. Eczema in old people called for special care in treatment, as their skin was particularly sensitive. Diabetic eczema, common about the genitals and groins, cleared up with elimination of sugar from urine. In the general treatment of eczema of internal origin it was advisable to search for foci of infection in teeth and tonsils. *B. coli* and *paratyphosus* and fæcal streptococci were often responsible, and vaccines were remarkably successful in some cases. Other cases responded to fasting and purging on a somewhat heroic scale. Dr. Little ordered Glauber's salts ʒx to be taken fasting in one pint of water first thing in the morning, and another pint or 2 pints of water during the first hour afterwards. This was followed by a complete fast, water only being allowed for 24, 36, or 48 hours according to the endurance of the patient. Lichen planus responded to this treatment like a charm. As to local treatment, for wet eczema he favoured wet dressings, such as saturated ac. boric dressings, or lotion of zinc sulphate and copper sulphate, aa gr. ii. aq. ad ℥i. For small patches silver nitrate 2 per cent. applied b.d. was often useful. After exudation had gone down, he believed in crude coal-tar ointment. This was specially useful for children. A common mistake was to put too heavy dressings on eczema, whereas small thin dressings to keep the eczema cool were indicated. Cold boric starch poultices were the most soothing of all applications. Dr. Little then described and showed cases of various forms of Lichen Planus.

Prof. F. LANGMEAD discussed

Some Functional Disorders in Young Children,

referring especially to three common functional disorders which often made a child's life miserable: (1) Nocturnal enuresis; (2) light terrors; (3) infantile convulsions. In *nocturnal enuresis* careful examination of the urine must be carried out to eliminate organic disease such as renal calculus, *B. coli* infection, highly acid urine, &c. Occasionally nocturnal epilepsy was found to be the unsuspected cause of nocturnal enuresis. It was advisable in cases found to be functional to classify children into: (1) The dull, apathetic, stupid, lethargic child; (2) the bright extra-intelligent scholar. Of these two classes Prof. Langmead thought the second variety was most commonly responsible for the children with enuresis. Treatment consisted first and foremost in the importance of training. The child should be held out at regular intervals during the first six months of his life, and excellent results would ensue. Highly acid urine should be alkalised. Tea must be prohibited. The child should sleep on a hard bed with plenty of fresh air in the room, when a slight stimulus to micturate would be more likely to wake him. As to drugs, in class 1 thyroid was beneficial, in class 2 belladonna pushed to toxic effects—i.e., dilatation of pupils in combination with bromides was advocated. *Night terrors* often depended on excitement just before bedtime, and over-fatigue and adventures in the daytime. The variety where the child did not remember his dreams on awaking was comparatively harmless. But the child who afterwards was aware of what happened during the night was liable to get a permanently damaged brain. Treatment consisted in elimination of excitement, never, in Prof. Langmead's opinion, in psychotherapy. *Infantile convulsions* and infantile eclampsia were really synonymous with epilepsy. Family history was of great assistance. Damage by forceps delivery, mental deficiency, intestinal disturbance, worms, and fevers had to be considered before one could term this condition functional. He particularly wished to warn his audience against prognosis in this class of case. The drug he found most successful in treatment was chloral hydrate gr. ii. pushed two hourly till the child became drowsy. Sometimes when this failed luminal gr. ½ b.d. was beneficial.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

University of Edinburgh.

IN the teaching of medicine and surgery in the Edinburgh University School a new plan has been adopted for all students who have yet to pass the pre-registration examination. It has been felt for some time that the old arrangement, whereby medicine and surgery were taught quite separately, respectively in the third and fourth winter, tended to give the student the impression that the two subjects were completely isolated, and it is hoped by the new scheme to give him a truer perspective of their essential inter-relation. Under the new curriculum, third-year students during the autumn term will receive, in addition to pathology and materia medica, a course of lectures in systematic medicine and an introductory course of clinical medicine, while in the spring term these will be replaced by similar courses in surgery. In the fourth year the students are to be divided into three groups: a medicine group, a surgery group, and a special subjects group (eye, ear, nose and throat, and skin diseases). In each of the three terms the student will change his group. In the spring term the systematic medicine lectures will be completed and in the summer term the systematic surgery lectures. In the fifth year a midwifery group replaces the special subjects group. The advantages of this scheme over the old one are fairly obvious. They should enable the student to advance his knowledge uniformly right up to the final examination.

Prof. J. J. R. McLeod (Toronto) will deliver the Cameron prize lecture in the University on Oct. 16th.

At a meeting of the Senators on Thursday, Oct. 4th, Prof. Thomas Jones Mackie, former Wernher-Beit professor of bacteriology, Cape Town University, was installed in the Irvine Chair of Bacteriology, left vacant through the death of the late Prof. James Ritchie.

Post-Graduate Medical Teaching in Glasgow.

The syllabus for winter session has now been issued. The scheme falls into three groups: Weekly demonstrations, special courses, and clinical assistantships. The series of demonstrations on Wednesday afternoons has been arranged on similar lines to those of former years. The range of subjects is a wide one—including medicine, surgery, obstetrics, and a number of special subjects. Demonstrations will be held each Wednesday afternoon at 4.15 from Nov. 7th, 1923, till May 28th, 1924, inclusive. In order to provide opportunities for more intensive and systematised post-graduate study, there have been arranged some special courses, dealing, for the most part, with two or more allied subjects. These include a course on the Mother and the New-born Infant, in which Prof. J. M. Munro Kerr, Dr. Leonard Findlay, Dr. D. Shannon, Dr. Jas. Hendry, and Dr. J. N. Cruickshank will take part. A course on Genito-Urinary Surgery, under Mr. M. Logan Taylor, Mr. J. Mill Renton, Mr. W. W. Galbraith, and Mr. J. G. McGregor Robertson; a course on Medical Ophthalmology conducted by members of the staffs of the Eye Infirmary, the Ophthalmic Institution, and the general hospitals; a course on Fractures, conducted by Mr. George H. Edington and Mr. Charles Bennett; and a course on Surgical Diseases of Children, by Mr. Alex. MacLennan.

Graduates who wish to enrol for any of these special courses or to become attached to wards or out-patient departments as clinical assistants, should communicate with, and pay their fees to, the Secretary, Post-Graduate Medical Association, The University, Glasgow.

The Morison Lectures.

The Morison lectures will be delivered on Oct. 15th, 16th, and 17th by Dr. Alexander Blackhall-Morison in the hall of the Royal College of Physicians, Queen-street, Edinburgh, at 5 P.M. The subject is: The Progress of Neurology, Psychology, and Psychiatry during the Century since the Foundation of the Lectureship.

THE LONDON MEDICAL EXHIBITION.

Both from the point of view of the number and variety of medical and surgical exhibits and from the large attendances, including many foreign medical visitors, the thirteenth London Medical Exhibition, which was held at the Central Hall, Westminster, from Oct. 1st to 5th, was an unqualified success, and that is saying much; but it also afforded a very practical indication of the rapid strides which medicine and surgery are making and the way in which manufacturers are endeavouring to supply the needs entailed by that progress. This was shown in the departments of electrical therapeutics, organotherapy, as well as in the direction of the new insulin treatment and the requirements involved in the "defatting" of bacteria. To fully describe all the exhibits of fine chemicals, surgical instruments, dental and optical appliances, and so forth, to mention only a part of the large field covered by the exhibition, would be impossible in the space at our disposal; but a brief summary of the chief features will show how rapidly the industrial part of scientific research has been organised since the war. Neither is any satisfactory classification of the exhibits possible, for commercial firms frequently represent more than one department of medicine or surgery. Roughly, however, the exhibition may be divided into drugs and food, instruments and appliances, milk, as being a special article of food, spas and waters, and medical books.

Drugs and Foods.

In the drug section Insulin attracted much attention. Allen and Hanburys, Ltd., of Lombard-street, London, E.C., Vere-street, W., and Wigmore-street, W., in addition to their surgical instruments, preparations for venereal treatment, organotherapeutic products, a new series of indicators for the colorimetric evaluation of hydrogen-ion concentration and for titrations, foods for infants, and diabetic flour, displayed Insulin A.B. Brand in vials of 5 c.cm. and 10 c.cm. In connexion with this new remedy a special set of apparatus and reagents for the estimation of blood-sugar by the Maclean method was shown, while for the benefit of the general practitioner who has little opportunity for keeping himself abreast of the most modern technique, special demonstrations were given almost continuously throughout the course of the exhibition and were remarkable for their crowded attendance.—Burroughs, Wellcome and Co., Snow Hill Buildings, London, E.C., also made a special feature of Insulin, and 11 stages in the Wellcome brand of the preparation from the ox pancreas to the finished product were shown. Preparations of the various glands for the production of the large assortment of tabloids which this firm make were exhibited, and maps and diagrams formed a very instructive and valuable exhibit. Particular stress was laid upon the use of Kharsivan and Neokharsivan in syphilis, yaws, and tropical ulcer; upon tabloid preparations for malaria; Moogrol for leprosy; and Soloid Antimony Tartrate for bilharziasis, kala-azar, and oriental sore.—Boots Pure Drug Company, Ltd., Nottingham, also demonstrated the blood-sugar test of Maclean, and exhibited a very large selection of synthetic chemicals, compressed tablets of medicinal drugs and chemicals, and pharmaceutical preparations in great variety. Chloramine T., Chloramine T. Surgical Paste, and Dichloramine T. were prominent exhibits, as were Flavine antiseptics and a fine selection of research chemicals.—Anglo-French Drug Co., Ltd., 238a, Gray's Inn-road, London, W.C., showed their Diabetylin for the treatment of diabetes mellitus without the withdrawal of carbohydrates from the dietary; Dimol, an intestinal disinfectant, Galyl for the treatment of syphilis, and many other pharmaceutical preparations, as well as the neoplastic reaction outfit for the differential diagnosis of cancer by the method of Thomas and Binetti.—The British Dyestuffs Corporation, Ltd., 70, Spring-gardens, Manchester, staged a fine selection of dyestuffs for medicinal use, microscopical stains, and materials for biological use. Euflavine, which this firm showed, is a neutral derivative of acriflavine, non-irritant even in concentrated solution, and is used in the treatment of gonorrhœa, infective skin diseases, and as a dental antiseptic.—Crookes Laboratories, 22, Chenies-street, London, W.C., exhibited in an attractive manner their colloidal drugs for medicinal use, and the "Brownian" activity of these preparations was strikingly shown under the microscope by dark-ground illumination. Among these drugs were Collosol Argentum, iodine, sulphur, and calcium, but special attention was drawn to Collosol Kaolin—a comminuted neutral powder in a very fine state of subdivision prepared by the precipitation of a colloidal suspension of china clay with the addition of 1 per cent. agar-agar. The claims for it are that it forms an adherent coating on the bowel wall, thus protecting the surface from irritant particles and digestive juices, an action which has led to its use in ulcerative colitis; secondly, that it possesses a remarkable power of adsorbing certain poisons, more particularly bacterial toxins, while not destroying micro-organisms or in any way affecting ferment action.—British Alkaloids, Ltd., 104, Winchester House, London, E.C., showed T.C.P. (trichlorophenyliodomethylsalicylic acid in H_2O), a germicide analgesic, antithermatic, keroplastic, non-hæmostatic, non-toxic, and non-caustic claimed to have high destructive germ action with a vitalising action on phagocytes.—British Organotherapy Co., Ltd., 22, Golden-square, London, W., attracted much attention by their complete range of monoglandular products, as well as by the polyglandular compounds, lymph serum, lymphoid compound, Ova Mammoid Compound, Ovatmine, and Pancreatokinase. The company also exhibited Sacchromycin, Anisothermal, isotonic and living yeast specially prepared for use in medical practice.—Angier Chemical Co., Ltd., 86, Clerkenwell-road, London E.C., exhibited Angier's Emulsion, each fluid ounce of which contains $33\frac{1}{3}$ per cent. of specially purified petroleum, and 9 gr. of combined hypophosphites of lime and soda with chemically pure glycerine.—Anglo-American Oil Company, Ltd., Albert-street, Camden Town, N.W., made a special feature of Nujol and Mistol, the former being an intestinal lubricant and the latter a solution of menthol, camphor, and eucalyptol in pure liquid paraffin indicated in catarrhal conditions of the mucous membrane of the nose and throat. It has also been found useful in the relief of hay fever.—The G. W. Carnrick Co.'s Standardised Gland Products (Agents, the American Drug Supply Co., Ltd., 40–42, Lexington-street, London, W.), exhibited dried extracts and powders of gland substances—Hormotone for menstrual and menopausal disorders, neurasthenia, &c., Trypsogen for diabetes mellitus, Secretogen for gastro-intestinal disorders, and Kinazyme as an aid to metabolism in tuberculosis, malnutrition, &c. All these products undergo a special laboratory test.—At the stall of Denver Chemical Manufacturing Co., London, E., Antiphlogistine, the well-known hygroscopic antiseptic poultice, was prominently displayed. Composed of anhydrous and levigated argillaceous mineral, pure glycerine, compounds of iodine, minute quantities of boric and salicylic acids, and the oils of peppermint, gaultheria, and eucalyptus, it is non-irritating and non-toxic, keeps in any climate, and is indicated for use in inflammatory and congested conditions.—Endocrines, Ltd., 72, Wigmore-street, London, W., showed a wide range of pluriglandular preparations, among 33 formulas being Adreno-Spermin Co., Thyro-Ovarian Co., and Pan Secretin Co.—C. J. Hewlett and Son, Ltd., 35–42, Charlotte-street, and 83–85, Curtain-road, London, E.C., among a large display of pharmaceutical preparations, showed their Antiseptic Cream, Hæmorrhaline (Ung. pro Hæmorrhoid), Hormonigen tablets containing the hormones of the thyroid, pituitary, ovary and testis, Ung. Iódermiol, prepared with lanoline and containing 5 per cent. of iodine, Liquor Santal Flav. c. Buchu et Cubeba, as well as improved surgical instruments, &c.—Laboratorie des Produits "Usines du Rhone" (Agents, Dick, Coates and Co., 41, Great Tower-street, London, E.C.), exhibited a wide range of pharmaceutical specialities, including Alunozal, ani ntestinal antiseptic; Asciatine, an antineuralgic, Scurenaline, a synthetic adrenalin; Scurocaine, a local anæsthetic; and Scuroforme, a local and internal anæsthetic.—Maltine Manufacturing Co., Ltd., 9, Holborn Viaduct, London, E.C., made a display of their well-known preparations of Maltine and Maltoline, the first containing the nutritive elements of wheat and oats, in addition to those of barley, and the second a combination of maltine, olive oil and phosphorus as an efficient alternative to cod-liver oil compounds.—Menley and James, Ltd., Menley House, Hatton-garden, London, W.C., called attention to their therapeutically active iodine in various forms.—W. Martindale, 10, New Cavendish-street, London, W., showed a wide range of medicinal preparations, including Aspriodine, a compound of aspirin and iodine, for use in asthma, enlarged glands, and arteriosclerosis; Emetine Periodide, which is relatively non-toxic and indicated in amœbic dysentery, as well as vaccines and reagents for microscopic research, blood-sugar estimation, and so forth. Attention may also be called to sodium chaulmoograte. Chaulmoogric has been fractionated by this firm into two main groups for internal and hypodermic use respectively in the treatment of leprosy and tuberculosis.—May and Baker, Ltd., Battersea, London, S.W., called special attention to stovaine solution in ampoules for spinal and local anæsthesia. It is claimed to be as effective as cocaine, while possessing about one-third of its toxicity. A large selection of antisyphilitics was also included in the exhibit of this firm, as well as general and local anæsthetics.—F. Newbery and Sons, Ltd., 27–28, Charterhouse-square, London, E.C., Cardiff and Liverpool, presented, in addition to Valentine's Meat Juice Phospho-lecithin (Wampole), a nerve food, reconstructive tonic, and protoplasmic regenerator of nerve tissue. Each dessertspoonful contains: sodium glycerophosphate, 2 gr.; calcium glycerophosphate, 1 gr.; potassium glycerophosphate, 1 gr.; strychnine glycerophosphate, 1–250 gr.; lecithin, 1–8 gr.; avenine, 1–120 gr. Bromo soda, which we have elsewhere stated agrees better than the potassium salt with some stomachs, is a bromide of sodium with caffein in granular form; and Ingluvin, the essential principle of the gizzard, for use where pepsine refuses to act, were other Wample preparations shown by this firm, who also exhibited Trommer Co.'s preparations, among others being their well-known elixir, malt, malt with cod-liver oil, and hypophosphates, pepsine, petroleum, and with cascara sagrada. An elegant and useful preparation also shown was pill cascara cathartic (Warner).—Oppenheimer, Son, and Co., Ltd., 179, Queen Victoria-street, London, E.C., in addition to Roboleine, the "A," "B," "C" vitamin diet, containing animal fats, maltose, diastase, natural nitrogenous and phosphoric compounds, with the "A," "B," "C" vitamins, made a special feature of organotherapy products, and their medicinal remedy for asthma Grindeline, each drachm of which contains: grindelia robusta liq. ext. (O.S. and Co.), ♏ 15; potassium iodide, gr. 2; trinitrin, gr. 1–200; euphorbia pilulifera tinct., ♏ 20. This firm supplies free to medical men a useful little pamphlet giving brief notes on the history and therapeutic uses of these drugs.—Parke, Davis and Co., 50, Beak-street, London, W., exhibited a wide range of pharmaceutical preparations. Among protein extracts for diagnosis there were more than 100 specific proteins (foods, pollen, hair, feathers, wool, bacteria, &c.), while among glandular preparations in the form of tablets were to be seen orchic compound, ovarian compound, suprarenal compound, thyorchic compound, and thyrovarian compound. A feature was also made of the vaccines prepared at St. Mary's Hospital, anti-catarrh and mixed vaccine for colds and mixed vaccine for bronchial asthma.—Charles H. Phillips Chemical Co., Acton Vale, W., displayed Milk of Magnesia and Phospho-muriate of Quinine Compound. —Sandoz Chemical Co., Ltd., Canal-road, Bradford, introduced to the notice of visitors their several preparations of Felamine, an association of biliary acids with hexamine, which is a cholagogue and disinfectant of biliary passages and intestines, as well as their Femergin, Scillaren, and Ipecopan, the latter being claimed to be superior to Dover's powder both in constancy and rapidity of action.—Savory and Moore, Ltd., 143, New Bond-street, London, W., had an interesting exhibit of their well-known preparations, including the food for infants, invalids, and convalescents, which approximates closely to human milk and contains the vitamins. Prominence was also given to Ethanesal, the underlying principle of which is ketones treated with carbon dioxide and ethylene with ether as a solvent.—Charles Zimmermann and Co., Ltd., 9 and 10, St. Mary-at-Hill, London, E.C., drew particular attention to Idozan, a colloidal iron used as an oxy-hæmoglobin excitant in the treatment of anæmia. The preparation of this substance has been based on the principle of ionisation and is stated to contain 5 per cent. of iron in a non-irritant form. It is a palatable preparation which does not blacken the teeth, and a large number of hæmoglobin charts were exhibited showing the marked rise during treatment and the fall when treatment was suspended. Chalybeate Medicinal Chocolate was another preparation shown by this firm. Each piece is equivalent to 3 gr. of iron.—Under the term Pineoleum, the Pineoleum Co., Inc. (Agents, American Drug Supply Co., Ltd., 40–42, Lexington Street, W.), exhibited a pleasant-smelling inhalant, standard sed and guaranteed chemically pure. It is indicated in irritation of the mucous membrane of the throat and nose where anodyne, antiseptic, and emollient action is required.

Pharmaceutical Supply Co., Ltd., 4–10, Hatfield-street, London, E.C., exhibited many useful hospital and nursing home requirements, and the Thermogene Co., Ltd., Victoria Embankment, London, showed their specially prepared cotton-wool, which, in suitable cases, possesses a distinct advantage over poultices.—Cuxson, Gerrard and Co., Ltd., Glasgow, had a useful selection of surgical ligatures and plasters, and also exhibited peptone.—Genatosan, Ltd. (British purchasers of the Sanatogen Co.), Loughborough, Leicestershire, exhibited their Sanatogen, an organic compound of casein and sodium glycero-phosphate Formamint, the well-known throat disinfectant, Genasprin, pure acetyl-salicylic acid, and Cystopurin, a urinary antiseptic containing undecomposed hexamethylenetetramine. This firm also showed detoxicated vaccines.—Oxo, Ltd., Thames House, Queen-street Place, London, E.C., displayed their well-known concentrated form of the stimulating extractive, together with easily digestible and nourishing constituents of fresh beef oxo, "oxo cubes," "hospital oxo," "lemco," and "gong" meat soups.—Virol, Ltd., Hanger-lane, Ealing, London, W., showed Virol and Virolax, the latter of which is now put up in a new form of package.—Vitmar, Ltd., 59, Standen-road, Southfields, London, S.W., showed the Callard's vitamin foods. The Vitmar supplied by this firm has been shown by biological experiments to contain the fat-soluble A and water-soluble B and C, and in addition to its use for the reinforcement of ordinary foods has been used as a galactagogue.—Bovril, Ltd., 148–166, Old-street, London, E.C., had a very attractive display of their Bovril and invalid Bovril, which is a highly concentrated pure preparation of beef whose nutritive value has been proved by long trial.—Newton, Chambers and Co., Ltd., 331, Gray's Inn-road, London, W.C., called attention to Izal for both medical and ordinary use as well as in its many forms as ointment, lozenges, soap, and so forth, and the "Zal" disinfector, an improved form of bronchitis kettle which can be used over a gas ring, spirit lamp, or other form of heat producer, and Jeyes' Sanitary Compounds Co., Ltd., 64, Cannon-street, London, E.C., showed their various preparations of Cyllin.—J. C. Eno, Ltd. (Eno's Fruit Salt), Victoria Embankment, London, E.C., showed their pleasant effervescent saline laxative, which is a combination of alkalies with fruit acids. Salts, such as sulphate of soda and magnesium compounds, are excluded, and care is taken that no trace of calcium, lead, or other common impurities exist in any of the ingredients.—Pepsodent Co., 42, Southwark Bridge-road, London, S.E., displayed their tooth paste, which is acidic in character and stimulates the salivary glands by reason of the contained acid calcium phosphates.—D. and W. Gibbs, Ltd., 105, High-street, Wapping, London, E., demonstrated the value of their dentifrice and dental cream and showed a variety of toilet soaps and a shaving soap, and Kolynos Inc., Chenies-street, London, W.C., displayed their well-known gritless dental cream.—Jaeger Co., Ltd., 95, Milton-street, London, E.C., exhibited pure wool clothing, and Bantum Products, Ltd., Farnley, Leeds, a preparation of coffee consisting of the soluble portion of that article.—Yomf Mfg. Co., 122, Greyhound-lane, Streatham, S.W., called attention to an antiseptic, detergent, and emollient cream for the hands when performing work that soils them, and C. R. Harker, Stagg and Morgan, Ltd., Devon Wharf, Emmott-street, Mile End, London, E., showed Peldo, an antiseptic cream for preventing dirt from penetrating the skin.

We shall deal with the remaining sections of the Exhibition in our next issue.

MINISTRY OF HEALTH.—Sir William Joynson-Hicks has appointed Lord Erskine to be his Parliamentary private secretary; Mr. Douglas Veale, of the Ministry of Health, to be his private secretary; and Mr. A. Nevil Rucker, also of the Ministry of Health, to be his assistant private secretary.

Congratulatory Messages.

The following additional congratulatory messages to The Lancet *on its Centenary have been received.*

So far as I know only two medical journals printed in English have passed their centenary, the *American Journal of the Medical Sciences* in Philadelphia, which achieved its centenary a few years ago, and now The Lancet, known all over the world, but especially in the English-speaking world. Its very name is historic, as it reminds us of a long abandoned but once almost universal treatment, while its content displays the most modern science. I have known and read it for over half its existence. It has ever stood in the front rank in labour for the good of the profession, for reform in our hospitals, and for their generous support by the public. I say " our " hospitals, for their world-wide reputation and influence for progress we in America are glad to recognise. The recent generous support given by the Rockefeller Foundation meets with an emphatic approval by our profession in America.

Long may its columns continue to be filled with the latest news in scientific and in practical medicine in all its branches. The older it grows may it ever show as it does to-day the vigour and elasticity of youth.

W. W. Keen,
Professor of Surgery, University of Philadelphia.

Will you extend to the proprietors and the staff and receive for yourself our felicitations at this time? While American physicians and surgeons naturally cannot appreciate certain services which this journal has undoubtedly rendered to the promotion of British medical enterprises, it is fully cognisant of the services it has rendered to the profession at large by the important contributions which have constantly appeared in its pages. With best wishes for the progress of The Lancet during its second centenary.

G. W. Crile,
Professor of Surgery, Cleveland, U.S.A.

May I add a word of congratulation to the many similar tributes you will have received? Though a layman, I have enjoyed the privilege of being more closely and intimately associated with your profession than any other man outside it, and for over 30 years The Lancet has proved a weekly source of enjoyment and education to me. The profession of medicine owes a debt of deep and lasting gratitude to The Lancet for its contribution during the past 100 years to the advancement of science, and the position which it occupies in the world of literature is one to be reflected upon with pardonable pride. You have my earnest good wishes for its continued prosperity, tendered in all sincerity.

W. E. Hempson.

Permit me to send to the whole staff and the proprietors of The Lancet my heartiest congratulations on the occasion of a centenary of a medical journal, and one which, during its existence, has always been the exponent of the noble and world-felt position held by British science generally and British medicine especially. Vivat, crescat, floreat!

Fully well understanding the honour of being

The Vienna Correspondent of The Lancet.

C'est une particulière joie pour le correspondant français du Lancet d'écrire dans ce numéro du Centenaire, et d'y indiquer combien les échanges intellectuels ont été intimes entre nos deux pays depuis un siècle et combien aussi ce journal y a contribué. Non seulement la réputation de Lancet est mondiale, mais pour le lecteur français, en dehors même du milieu médical où son éloge n'est plus à faire, il représente le type du journal médical anglais, la tradition britannique, qui sait si bien se renouveler en gardant son cadre, ouvrir ses colonnes aux idées neuves, se lancer dans des voies nouvelles, et rester malgré cela elle-même. C'est par l'élite dirigeante d'une nation que se font les rapprochements, et rien n'est plus propre à créer une " entente " que d'échanger des points de vue scientifiques, de confronter des méthodes. C'est à cela que s'est employé le Lancet en instituant des 1830 des comptes rendus des travaux originaux français, et des traditions des conférences cliniques et pathologiques de nos hôpitaux.

Orfila, Andral, Dupuytren, Magendie furent les collaborateurs du journal, et c'est aussi dans ces premières années qu'eurent lieu les mémorables discussions sur le système phrénologique de Gall, auquel Bell et Brodie firent une opposition, si intelligente et si ferme. Cette collaboration franco-anglaise n'a pas cessé et actuellement parait régulièrement un supplément français dirigé par le Professeur Achard. En dehors de ces travaux réellement scientifiques, le Lancet tenait ses lecteurs au courant des évènements français, par les lettres de son correspondant parisien, chargé de renseigner le public médical anglais sur tous les faits qui touchent la médecine, de près ou de loin. C'est donc une collaboration intime qui depuis bientôt un siècle a relié le Lancet et la médecine française. Si par l'intermédiaire de ce journal les idées françaises pénétraient en Angleterre, c'est aussi par lui que les idées anglaises influaient chez nous. Comme je le notais au début de cet article, le Lancet a pris en France, droit de cité pour le public médical français il représente le journal type, et les traductions de ses articles originaux qui paraissent régulièrement dans tous nos grands journaux médicaux, sont toujours recherchées. C'est encore à lui qu'on a recours si on veut se renseigner sur les travaux anglais, on recherchera d'avoir là, ce qu'on veut trouver.

Mais en sortant du domaine propre des travaux ou des recherches médicales, on peut se demander qu'elle a été de puis un siècle, l'influence d'un journal médical anglais, sur nos idées. La science française se manifeste toujours par un point de vue original, en médecine comme en beaucoup d'autres sciences d'ailleurs il y a une idée française, toute différente de l'idée allemande par exemple et souvent opposée. Plus d'imagination, l'habitude d'envisager les faits d'un point de vue plus élevé, plus général, donne à la médecine française une allure qui lui est bien personnelle. Il est donc particulièrement intéressant de la voir traduite, comprise, et interprêtée par le miroir anglais, le Lancet nous renvoie notre image modifiée, adaptée à son nouveau cadre. Presque toujours cette adaptation a pris une forme pratique, et c'est, je le crois le sens le plus net de l'influence anglaise sur la science médicale française. Aussi cette influence s'est elle exercée surtout dans le domaine de l'hygiène et de l'éducation, où, dans ces dernières années particulièrement, nous retrouvons constamment un courant d'anglicisation. Il serait à souhaiter que les relations médicales franco-anglaises soient de plus en plus fréquentes, de part et d'autres, nous aurions grand profit à échanger nos idées.

Les conférences de professeurs, qui, l'an dernier, ont été organisées à Paris et à Londres, sont le début de ce contact plus parfait entre deux pays, où l'entente peut être aussi intellectuelle que cordiale.

Your Paris Correspondent.

Allow me to congratulate you, the staff, and the publishers of The Lancet upon the occasion of your Centenary. It has been a great satisfaction to me to be connected with The Lancet for a long course of years, and I hope that this connexion will maintain the friendly relations which have prevailed hitherto.

Your Berlin Correspondent.

POST-HOLIDAY LASSITUDE.

To the Editor of THE LANCET.

SIR,—Your leading article of Sept. 1st last deals with a subject that is of special interest at this time of the year, when so many people, returning from their holidays and getting back to their old routine, find to their disappointment that, sunburnt and muscular as they may be, they are even less inclined for work than when they went away to recuperate. And the more extended the holiday the more apt is this lassitude to occur, and one often hears men remark that if they only stayed away a bit longer they would never want to work again.

The suggestion is made by you that this limpness may be due to the blood destruction that takes place during unusual exercise, and you quote Dr. G. O. Broun's work on dogs in support of this. Dr. Broun found that when dogs that had for long lived a sedentary life along with a generous diet were subjected to severe exercise for several days they appeared to be very tired at first, and an examination of the blood, repeated at frequent intervals before, during, and after the exertion, showed that the total corpuscular volume was greatly decreased by the exercise and that it took from one to three weeks to regain its former state. Evidently the blood cells are in some way destroyed during the exercise when this is undertaken by well-fed animals not used to it. The changes do not occur in dogs that have already been living an active and abstemious life. There seems, then, to be no doubt that severe exercise in sedentary, well-fed animals produces blood changes, but it is a long jump to thus explain the post-holiday lassitude (of the existence of which there is no doubt) as being due to such blood changes. It was noted by Dr. Broun that "in the early days of the experiment the dogs appeared tired, but by the end they showed all the signs of thorough enjoyment." And yet the blood changes persist for one to three weeks after the exertion is over. A man who has been on an active holiday for, say, a month feels very fit at the end of the pleasant experiment (just like the dogs), and it is not until the holiday is over and he is back at the old grind that the lassitude appears. Possibly the tired feeling on Monday morning after a too vigorous week-end may be explained in the way that you suggest, but I am speaking of holidays of longer duration than this.

To my mind, the post-holiday lassitude is, as you mention, chiefly psychic, but no doubt is also in part due to the fact that the man has become used to much exercise and now misses it, and, moreover, he has probably picked up a good appetite during his wanderings and now eats more than is required to meet the caloric requirements of his resumed quiet life, and hence suffers accordingly. Dr. Broun's dogs were worst in the early days of their holiday [sic]; the human animal only feels the lassitude after the holiday is over.

I am, Sir, yours faithfully,

Toronto, Canada, Sept. 24th, 1923. R. D. RUDOLF.

UNIVERSITY PATHOLOGICAL DEPARTMENTS.

To the Editor of THE LANCET.

SIR,—It is evident that there is little to be said in favour of university pathological and bacteriological departments carrying on outside work, since your leading article has only elicited a half-hearted defence from Prof. J. W. McLeod, whose arguments would apply equally to several other university departments; I should like to ask him if he would approve of a university carrying on the work of a public analyst through its chemical department. I do not suppose that any university would dream of doing such a thing, the reason being that, as I stated in my previous letter, universities regard chemistry as a science, while they do not so regard pathology. May I suggest a further point—that professors of pathology and bacteriology should show a little sympathy with those who wish to earn a living by the practice of pathology, although they are not attached to a university laboratory.

I am, Sir, yours faithfully,

CHARLES POWELL WHITE.

Manchester, Oct. 3rd, 1923.

To the Editor of THE LANCET.

SIR,—A pathological department in a university ought to strive to attract all real workers in pathology in or around that centre who, in addition to their routine work, desire to have the fuller facilities for research work on lines which are difficult to achieve in this country in the smaller laboratories. They should not feel that they are entering the portals of a rival institution, but rather that they are returning to their Alma Mater to further in their spare time the claims of research and humanity.

As one who has had to strive for a living in pathology I should like to record my opinion that it is unfair that universities should in virtue of their endowments endeavour to oust the smaller laboratories and gain a monopoly not only of private pathological work, but of public health work. It is not always a question of cost which is concerned, since many of the smaller laboratories are run far more economically than the larger ones without any real loss of efficiency. It is easy, however, for university authorities to influence the payment to them of large sums for public health work which could have been done quite as well and quite as economically by other laboratories. The smaller laboratories to-day are as essential to the community as are the larger laboratories, and they should be encouraged by their university colleagues rather than suppressed.

I am, Sir, yours faithfully,

Manchester, Oct. 3rd, 1923. ARNOLD RENSHAW.

LICE AND CRIME.

To the Editor of THE LANCET.

SIR,—Recently there has appeared in the press an important statement by the Society for the Repression of Vermin showing the enormous sums of money rats and mice cost us. I want now to call attention to the perhaps even greater mischief done by smaller vermin—lice—and their connexion with crime.

1. The three great causes of crime are drink, gambling, and destitution. Many persons steal or beg from destitution and because they will not go into the workhouse or the more hated casual ward. And some break windows or do other "malicious" damage, so that they may be sent to prison. Others, if in workhouse or casual ward, will refuse to work, tear up their clothes, or commit some other "workhouse offence" with the same object. And a few quite quietly starve to death. Now I have been told that to the more decent men on the road, the most detestable feature of some of the casual wards is the prevalence of lice. This disgusting condition is quite needless, because other casual wards are *not* "lousy," and are quite decent. The remedy is simple. The new Minister of Health, Sir W. Joynson Hicks, is about to issue a new Order for the casual wards. This Order should contain definite and detailed provisions for the cleanliness of the beds and clothing and bathing arrangements and general accommodation of the casual wards; and it should be declared that it is the duty of the inspectors to see that they are carried out. As an additional security, I would suggest that the magistrates should use their almost forgotten powers of visiting the wards given by the Workhouse Act, 1790, and the Poor-law Act of 1834.

2. A considerable number of persons are convicted every year for not sending their children to school. When many of these cases come before the court it is

shown that the children have been sent to school, but in such a lousy condition that they are (very properly) sent back, and instructions for cleaning given which the parents have not carried out.

3. I will not lengthen this letter by any suggestions how to deal with these latter cases, but wish to emphasise the necessity of efforts to exterminate these vermin in the casual wards and elsewhere on account of their being a cause of crime as well as inflicting serious injury to comfort and self-respect. And really to offer lousy casual wards to ex-soldiers is the deepest ingratitude. Of course it is not only the lice in the wards which push men into crime; there is also the wretched food and (in some wards) the cruel task. The new Order should amend the treatment in these respects.

4. I should be glad if you can add the following figures of persons tried in courts of summary jurisdiction in 1921—the latest available: Begging, 4313; sleeping out, 2923; misbehaviour of paupers, 459; stealing or destroying workhouse clothes, 130. It is alarming to see how these figures have risen since 1917.

The figure for malicious damage is 10,317; for simple larceny and minor larcenies, 40,992; and for offences against the Education Acts, 26,529.

I am, Sir, yours faithfully,

Oxford, Sept. 29th, 1923. J. THEODORE DODD.

THE LATE MR. H. D. FARNELL.

To the Editor of THE LANCET.

SIR,—I wish to add a word or two to the excellent obituary notice of Mr. Farnell, of Eastbourne. He was a fellow student of mine and a fellow resident in old days, and we were staunch friends throughout his professional life, and I can bear witness to the singular unity of his character and career from first to last. He was always alert, quick at the uptake, seizing at once the salient features of any case. He arrived at his conclusions rapidly, and they were based on sound premises. In those early days he had undoubted charm; he was cheery and friendly alike with patient, fellow student, and chief. There were few residents so popular and few so modest and yet inspiring. All these qualities were characteristic of Farnell throughout his happy and busy life. He never spared himself. It is no wonder that his faculty of rapid and effective investigation, his marked power of concentration and decision in stating his conclusions, combined with real sympathy, made him a very successful practitioner. He was always bon camarade. I should think it never occurred to him to ascribe unworthy motives to his fellows. In medical societies and all joint efforts for the good of his profession he was keen, indefatigable, and possessed of remarkably good judgment.

It is needless to say that everybody who met Farnell in his home very soon realised what a good husband and tender father he was. He had in no scant measure the very genius of friendship.

I am, Sir, yours faithfully,

Sept. 28th, 1923. THOMAS BARLOW.

STRIÆ DISTENSÆ.

To the Editor of THE LANCET.

SIR,—In your issue of Sept. 1st Dr. Bedo Hobbs states that it is probable that the two conditions—striæ distensæ and lineæ gravidarum—are not identical. He bases this assumption on: 1. Age-period strictly limited in striæ distensæ. 2. "The striæ gravidarum are pinkish-white in appearance even when first formed and never present the livid purple colour of striæ distensæ, which seems to indicate a more profound change." 3. That "one might argue that the general nutrition of the body, including the skin, is lowered during pregnancy, and that the pressure of tight clothing on the distended abdomen acts in the same way as the pressure produced by lying in one position." He refers to one group of cases in which large deposits of fat are *rapidly* laid down.

In subcutaneous œdema and in those with striæ above the patella, &c., are cases in which the skin is suddenly stretched and remain so for some time with no relaxation. It is here that the livid purple coloration is noticed and may be compared with the result of tension sutures used in abdominal (chiefly) operations, where frequently one observes dark blue or purple discoloration at the site of the sutures, due to *sudden* and prolonged stretching of the skin. Lineæ gravidarum occurs as the result of *slow* progressive enlargement, and where, as a result of the slowness of the process, the nutrition of the skin is not impaired and the blue discoloration (which is the sign of impairment) does not occur. I would suggest that herein only lies the difference between the two conditions. I am, Sir, yours faithfully,

Swansea, Sept. 28th, 1923. H. SPENCER-DAVIES.

CANCER AND DIET.

To the Editor of THE LANCET.

SIR,—Referring to Dr. Monckton Copeman's statements in THE LANCET of Sept. 29th as to the effect of modified diets in cases of cancer, I should like to point out that many years ago the late Dr. Mortimer, of Exeter, one of the most observant general practitioners I have ever met, pointed out to me the good effects of denying meat as an article of diet in inoperable cases of cancer. I have since in such cases advised that this rule should be followed and have in a considerable number of cases heard from the practitioners concerned that in their opinion this practice had proved beneficial. I think it is especially useful in the elderly.

I am, Sir, yours faithfully,

Exeter, Sept. 30th, 1923. RUSSELL COOMBE.

THE TUBERCULIN DISPENSARY FOR THE POOR.

To the Editor of THE LANCET.

SIR,—In your review of Dr. Camac Wilkinson's book on this subject in THE LANCET of Sept. 8th, some statistics of mine were subjected to a certain amount of criticism to which, perhaps, I may be permitted briefly to reply. I regret that my short article [1] did not appear explicit enough as to the method of selection of cases, which, as the reviewer not unreasonably states, is a most important factor to be considered in coming to any conclusion.

The sole method of selection of cases was the ability of the patient to attend the central dispensary twice a week for treatment and was not determined in any way by temperature or physical signs. Patients "on the books" of the six or seven outlying dispensaries were not treated by tuberculin for the simple reason that it was impossible in an area of about 25 miles radius for one tuberculosis officer to attend frequently enough to administer the tuberculin. The central dispensary at Oxford was really a tuberculin dispensary. At it were treated with tuberculin every patient who could attend regularly. In my figures are included cases of advanced disease who received a few injections only, cases which in the light of greater clinical experience would not now be subjected to tuberculin treatment and which, at varying periods in the natural progress of the disease, were no longer able to attend. These cases obviously reduce the percentage of good results and explain the difference between my figures and those of Dr. Wilkinson [2] where, of patients in stage 1 and stage 2 of the disease nine years after treatment, 72 per cent. were still alive and able to work. Those of us who have used his method of tuberculin administration are prepared to accept his figures and would welcome further inquiries, as you suggest, into the action of a remedy which we believe to be at once more efficient and much more economical than the methods at present employed in the treatment of lung tuberculosis.

There is much yet to be learned about tuberculin. It may be that Prof. Dreyer's antigen will solve the difficulties in treating the third stage cases, although previous "defatted" tuberculin, in small doses, have met with little success. Better results in the first and second stages of the disease can hardly be expected than those published by Dr. Wilkinson.

---

[1] Brit. Med. Jour., Lond., Sept. 9th, 1922, 473.

[2] Ibid., April 21st, 1923.

In conclusion, I should like to state that my work with tuberculin was carried out independently of Dr. Wilkinson, with whom I had no association from the time I began using his method till quite recently, prior to his departure for a prolonged holiday abroad.

I am, Sir, yours faithfully,

Oxford, Oct. 3rd, 1923. WILLIAM STOBIE.

PS.—All cases referred to were sputum positive.

COW'S MILK IN INFANT FEEDING: A CORRECTION.

To the Editor of THE LANCET.

SIR,—May I call your attention to a mistake in THE LANCET of August 18th (p. 361) in the report on my paper, Cow's Milk in Infant Feeding, which was read in the Children's Section of the British Medical Association annual meeting at Portsmouth on July 26th.

I am reported to have said that *spray* process milk powders formed a curd with rennet similar to human milk, were rich in vitamins, &c. My paper was published in the *British Medical Journal* of August 25th, and reference to p. 324 of that issue gives my words: "Whereas the addition of rennet to reconstituted milk prepared by the former process (the roller method) produces a fine flocculent curd, *its addition to a solution of spray process milk powder forms a dense mass identical with that formed in raw milk.*" My remarks as to vitamins applied to dry milk generally and not to spray milk. Your report has misrepresented facts which probably are well known to all who have studied the subject.

I am, Sir, yours faithfully,

Harley-street, W. R. J. BLACKHAM.

*** We regret the error, which, as our correspondent says, must have been detected by students of the subject.—ED. L.

Obituary.

THE LATE SIR HALLIDAY CROOM.

WITH the death of Sir Halliday Croom, which was chronicled last week, there passed away the last link between the present and the days of Edinburgh's unassailed pre-eminence as a medical school, the days of Syme, Lister, and Simpson. It is probably true to say that since the death of Simpson no death in the Edinburgh medical world has left such a gap, and Croom probably rivalled Lister in the affectionate esteem and regard in which he was held by his students. It is essentially as a teacher that Sir Halliday Croom will be remembered. When in 1878 Dr. Croom, as he then was, began lecturing on midwifery and diseases of women in the extra-mural school in Minto-street his success was immediate. From that time to his retirement from the Chair of Midwifery in 1921 he devoted himself heart and soul with almost religious fervour to his teaching, and to his power will testify every student who passed through his hands. Croom was the first man in Edinburgh to deliver post-graduate lectures, and the story is told of the effect of one of them on an American doctor. The lecture was on extra-uterine pregnancy, and on being asked what he thought of it, the doctor exclaimed, "I guess he makes you feel that the welfare of your mortal soul depends on your knowledge of extra-uterine pregnancy." The story well illustrates the impressive personality of the man, his wonderful histrionic gifts, and his unflagging enthusiasm. In the pains and rouble he took with his teaching he must be without ival. On the mornings on which he was to deliver a clinical lecture he would do no other work before it, but spent all the time in preparation, and every one of his systematic lectures was freshly prepared. He had a great facility for picking out the salient points of a case and driving them home with happy illustrations. It was in the spirit of the Hippocratic Oath that he taught, imparting his knowledge to others as a sacred duty, and he was always happiest and at his best when lecturing to an audience of students whom he knew personally. He was ever a staunch friend of his students, many of whom have reason to remember his friendship in deep gratitude. It has been said that his strength was his weakness; that had he devoted to investigation some of the energy he imparted to his teaching he might have added more greatly to the scientific knowledge of his specialty. But the neglect of his great gift would have been sinful. He improved his talent with ceaseless endeavour, and the far-reaching effects of his life's unselfish work no man can gauge. Like all great men, Croom had his foibles. He was particularly proud of his handwriting, and used to take the most meticulous care over his signature. He always lectured in a swallow-tailed coat—the same one. It was his prophet's mantle. When he assumed it the suave, courteous physician became the inspired teacher. Croom felt his retirement from the Chair of Midwifery most keenly, and he confessed that, after he had given up his teaching which had become so essential a part of his life, he felt like a wandering ghost. In the end no doubt, although he remained optimistic and hopeful, he was not altogether sorry to lay down a life well spent.

To the above appreciation of an old pupil we add a personal tribute from his friend and colleague, Dr. A. F. Barbour, who writes: "Sir Halliday Croom was the most considerate of colleagues and a very true friend. He had a charming personality, sensitive to the attitude of others and to the graces of life, careful of those small courtesies which make the wheels run smoothly, were it an exquisitely spaced, penned, and worded line of congratulation, of apology or direction; happy to advance the interests of a friend, desperately unwilling to hurt or offend the least intimate or the most undeserving. Many will remember the gracious host who tactfully and cordially made each guest welcome and was never so intent on his own good story as to fail in drawing out from others their opinions and information. For a long term of years we were intimately associated as colleagues in the Infirmary, Maternity Hospital, and University; few can look back with greater pleasure on a longer period of work together, and during it all the wonderful courtesy and consideration of Croom made one glad to have been one of his friends. As revealing depths not reached by the casual acquaintance, I may be allowed to add a sentence from his last letter, one of many received during our years of intercourse: 'I think few men can look back with greater pleasure upon a long memory of association. *Fiat voluntas Tua.* The night has come, I can hardly realise the day is past.' And this from a letter to another intimate friend: 'As one gets older one's creed gets simpler. I am grateful to God for all his mercies and endless forbearance, and my hope and belief are that that mercy and forbearance will be extended to us in the world beyond. For I feel sure that when that wondrous hour comes when the road leads down to the last slope which we must all follow, and I come near the dark waters over which the evening mist hangs thick, I shall find that faithful friend whom I have so often forgotten and wronged waiting near at hand to give me a last word of cheer, or, it is just possible a word of welcome as I set my foot on the shore which is so far off and yet so near.'"

SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS.—An ordinary meeting of this Society will be held at 122, Harley-street, at 4 P.M. on Oct. 15th, when a discussion on Thoracoplasty will be introduced by Mr. W. H. C. Romanis, and a final report will be submitted by the committee to which was referred the question of the training of tuberculosis nurses.

Medical News.

UNIVERSITY OF LONDON.—A course of eight lectures on the Histology of the Nervous System is being given by Dr. C. Da Fano at King's College, Strand, W.C. 2, at 4.30 P.M., on Wednesdays. The course began on Oct. 10th. A course of eight lectures on Newer Aspects of Nutrition is being given by Prof. V. H. Mottram at King's College for Women, 61, Campden Hill-road, W. 8, at 5 P.M., on Mondays. The course began on Oct. 8th. Attendance at either course is recognised in connexion with the B.Sc. (Honours) degree in physiology, and admission is free.

University College.—Dr. A. V. Hill, the newly elected Jodrell Professor of Physiology, will give a public inaugural lecture on the Present Tendencies and Future Compass of Physiological Science on Tuesday, Oct. 16th, at 5.30 P.M. The lecture will be held in the theatre of the new anatomy building at University College, and Prof. E. H. Starling will take the chair. Cards of admission will be sent on application to the secretary of the College; such applications should be accompanied with a stamped addressed envelope. The new anatomy building will be open to inspection as from 4.30 that afternoon.

UNIVERSITY OF SHEFFIELD.—The diploma in Public Health of this University has been awarded to Samuel Bryson and Patrick Kane.

UNIVERSITY OF BRISTOL.—A post-graduate demonstration will be held at Swindon on Oct. 17th, when Mr. C. F. Walters will discuss Differentiation of the Acute Abdomen and its Simulators.

PSYCHOLOGY AND PSYCHOTHERAPY.—A course of seven public lectures on this subject will be given in the Examination Schools at Oxford by the Wilde Reader in Mental Philosophy, Dr. William Brown, on Mondays, at 5.45 P.M., commencing Monday, Oct. 15th.

FEDERATION OF MEDICAL AND ALLIED SERVICES.—On Wednesday, Oct. 24th, at 4 P.M., a Conference will be held at the offices of the Federation, 12, Stratford-place, London, W., the question to be debated being the utility of a periodical medical overhaul of life policies. It is suggested that holders of policies willing to submit and pay for such scrutinies might be able to obtain more favourable terms from insurance companies, and that companies might like to obtain up-to-date information as to their risks.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The demonstrations, open to advanced students and medical practitioners, of specimens in the Museum commenced in the theatre of the College in Lincoln's Inn Fields on Oct. 12th, at 5 P.M., when Sir Arthur Keith showed specimens illustrating hernial formations of an acquired nature which form at various points of the alimentary canal and at other sites; on Oct. 19th, at the same time, those illustrating hernial formations of developmental origin which occur along the alimentary and respiratory tracts will be dealt with; and on Oct. 26th he will demonstrate the distinction between congenital and acquired forms of true hernia. On Oct. 15th, at 5 P.M., Prof. S. G. Shattock will show specimens illustrating necrosis, on Oct. 22nd those illustrating arteries; and on Oct 29th actinomycosis and madura disease.

GUY'S HOSPITAL MEDICAL SCHOOL.—The following scholarships have been awarded:—Open Scholarship in Arts: Mr. W. S. Baxter, Foyle College, Londonderry, and Mr. J. W. Crow, Charterhouse, £50 each. Scholarships for University Students: War Memorial Scholarship, Mr. D. Lurie, Oxford, £80; Open Scholarship, Mr. W. D. B. Read, Oxford, £80. Scholarships in Junior Science: Confined Scholarship, Mr. E. T. Conybeare, Plymouth College and Guy's, £100; Open Scholarship, Mr. R. E. Fossey, Brighton Grammar School and Guy's; E. M. Sharples, Queen's College, British Guiana, £50 each.

Guy's Hospital Dental School.—War Memorial Scholarship in Arts: D. C. Buckley, King's College, London, and Guy's; W. P. Roe, University College School, £20 per annum each for four years. Junior Science Scholarship: F. S. Warner, Guy's, £20 per annum for two years; N. C. Yendell, Clifton College and Guy's, £20 per annum for three and a quarter years.

ST. GEORGE'S HOSPITAL.—The annual dinner of the School and Hospital was held on Oct. 1st at the New Metropole Hotel, when Mr. E. B. Turner presided over a representative body of guests. The occasion was taken by the chairman and Lord Greville, the hon. treasurer of the Hospital, to tell the audience in straightforward and simple fashion the present position of affairs at the Hospital, especially in reference to the school. The note of Mr. Turner's speech was the necessity of an intimate connexion at a hospital like St. George's between the charitable and clinical work and the educational institution. The Dean of the Hospital, Dr. J. A. Torrens, in a quietly humorous speech, accented the points made by showing the recent progress in numbers of the school, the very high level of examinational successes, and by alluding pointedly to the reappearance of St. George's again in the athletic arena. Lord Greville said that the Governors of the Hospital had under immediate consideration many things for the improvement of the institution both as a hospital and a teaching school, though the difficulty of raising money at the present moment compelled them to go slowly, but all present who knew their institution were delighted to hear that the first of these schemes was likely to be a large rearrangement of the out-patient department. The treasurer pointed out that although the Hospital is placed on what is probably the most expensive residential site in London it possesses the houses adjoining the present building, so that the most difficult preliminary in the extension of public buildings—namely, the acquisition of the surrounding land, is obviated. Amusing speeches from Sir George Turner, consulting surgeon to the Hospital, and Sir Malcolm Morris, replying for the guests, brought a pleasant evening to a conclusion.

THE annual Harveian commemoration dinner of the Royal College of Physicians of London will be held at the College on Oct. 18th, at 7.30 P.M.

THE chairman and members of Council of the British Medical Association with their guests will dine at the Hotel Victoria (Edward VII. Room), London, on Wednesday, Oct. 24th, at 7 for 7.30 P.M.

THE old students' dinner of St. Thomas's Hospital, London, will be held at the Princes' Restaurant, Piccadilly, on Friday, Oct. 26th, at 7 for 7.30 P.M., Mr. W. H. Battle in the chair.

THE dinner of the Chelsea Clinical Society will take place at the Café Royal, Regent-street, London, on Oct. 30th, at 7 for 7.30 P.M. The hon. secretary is Dr. P. Seymour Price, 41, Sloane-gardens, S.W. 1.

WESTMINSTER HOSPITAL.—The annual dinner of past and present students of Westminster Hospital wa held at the Trocadero Restaurant on Oct. 4th, Mr. Walte Spencer, the senior surgeon, in the chair. In giving the toas of the Hospital and Medical School he reminded his audienc that Westminster had now entered on its third century o existence in the neighbourhood in which it was founded. The voluntary system had persisted throughout, and ther was, he felt sure, every prospect of a continuance if the appea shortly to be made to meet the cost of rebuilding wa successful. The new building would have 235 beds, wit new special departments, operating theatres, and improvements of every necessary kind. In giving the toast, Mr Spencer coupled with it the name of Dr. A. S. Woodwark Dean of the Medical School. Dr. Woodwark, in his reply described the condition of the school as satisfactory in ever way. Each year since the war had witnessed a stead increase in the number of students, a succession of examina tion pass lists which compared well with those of any othe medical school in the metropolis, and a gradual return t pre-war conditions as regards social and athletic activiti Sir James Purves-Stewart proposed The Universities, an in their replies Sir Archibald Garrod gave a résumé of th relation of biochemistry to clinical practice, and Sir Cliffor Allbutt drew an optimistic picture of the possibilities an opportunities open to those who preferred to devote themselves to the more academic side of their profession. Mr H. J. Waring and Prof. David Hepburn also responded Mr. William Turner proposed The Past and Present Student adding that this, generally the most popular toast of th evening, was on this occasion superseded by that of th chairman to come later, to whose retirement he referred i sympathetic terms. He coupled with the toast the name of Dr. Robert Nimmo Watson, who had most patriotical come all the way from Harrogate, and Mr. R. A. Hicklin Dr. Watson voiced the sentiments of the men in genera practice, who had known Mr. Spencer throughout the whol of their career, and had found every year more reasons t express their gratitude. Mr. Hickling, representing th present students, said that the only thing to complete the satisfaction would be the provision of an athletic ground their own. Mr. Arthur Evans, in proposing The Visitor coupled with the toast the name of the Rev. Harold Costle White, Headmaster of Westminster School; in respons Mr. Costley-White stated that as a school master he ha always felt that for a medical career a boy required a ver early preparation, psychically as well as academicall

Dr. F. de Havilland Hall, with many affectionate references, proposed The Chairman, his old colleague, now retiring from the staff of the hospital which he had served so loyally for 35 years. Mr. Spencer briefly replied.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The annual dinner will be held at the Hotel Cecil, Strand, London, W.C., on Oct. 19th. The President, Dr. T. W. Naylor Barlow, and Mrs. Barlow will receive the guests at 7.10 P.M., and dinner will be served at 7.30. Amongst those who have already accepted invitations are the Minister of Health, Sir Arthur Robinson, Sir Humphry Rolleston, Lord Riddell, Sir George Newman, Sir Dawson Williams, Mr. Justice Swift, and Sir Squire Sprigge. Members are asked to give early notice to the executive secretary at 1, Upper Montague-street, Russell-square, London, W.C. 1, of their intention to be present. Tickets 12*s.* 6*d.* each.

PRINCE OF WALES HOSPITAL.—The annual dinner of the Reunion Association will be held at Pagani's Restaurant, Great Portland-street, London, W., on Nov. 8th, at 7.30 for 8 P.M. The chair will be taken by Dr. George Chappel. The price of the dinner will be 12*s.* 6*d.* (exclusive of wine) for members and their guests. The secretaries are Dr. Jenkins Oliver, 1, Devonshire-place, London, W. 1, and Mr. S. O. Rashbrook, 7, Wellesley-road Chiswick, London, W. 4.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—The annual dinner of past and present students was held in the Connaught Rooms on Oct. 1st, when Mr. V. Warren Low presided over a large and representative gathering. Among the guests were the Vice-Chancellor of the University of London, the Director-General of the Royal Naval Medical Service, the Director-General of the Royal Army Medical Service, and the Mayor of Paddington. In proposing the toast of the Hospital and Medical School, Mr. Warren Low, who had a great reception, recalled the many distinguished men who had helped to build up St. Mary's, and expressed the opinion that 80 years was a very good kind of age for a medical school to be. Replying for the hospital, Mr. A. R. Prideaux, chairman of the board of management, was able to give a satisfactory account of the financial position of the hospital, a happy state of affairs due in no small part to the cordial coöperation between the staff of the hospital and the lay members of the board. Dr. C. M. Wilson, the Dean, gave an equally cheerful account of the position of the medical school. Though the entries at medical schools throughout the country showed signs of falling, the numbers at St. Mary's were higher than they ever had been. By arrangement with Queen Charlotte's Hospital, St. Mary's students now attended there for a period of instruction in midwifery, and this, combined with the facilities already afforded by the labour wards and the large district served by St. Mary's, made the teaching in this branch of the curriculum beyond reproach. In other respects, notably in the class of the primary Fellowship examination, academic achievement reached a high level, and there was a welcome vigour in athletic circles. A pleasant episode was the brief and happy speech of Dr. Milner-Moore, the doyen of St. Mary's men, who attended the inaugural dinner in the early "sixties." The official proceedings closed with the toast of the chairman, proposed by Mr. Herbert Waring and received with musical honours.

MEDICAL DEFENCE UNION.—The annual general meeting was held at the Royal Hotel, College Green, Bristol, on Sept. 29th, Sir Charles Ballance, the President, occupied the chair. In moving the adoption of the annual report of the Council for the year 1922–23, the President said that he was glad to be able to congratulate the members upon the continued expansion and satisfactory progress of the Union. On only one previous occasion had the annual meeting been held in Bristol, and that was 14 years ago. At that time the membership was approximately 7700. Now it was over 10,700. The income of the Union then was only a little over £4000. Now it was over £10,000, and with this improvement in the financial position the Union was able to do far more for its members than formerly. Every additional member meant greater protection for all, and medical practitioners should realise that in joining the Union they were not only protecting their own interests, but were doing something for others. The report showed that one noticeable feature of the last few years had been the increase in the number of women members. Over 400 women doctors have now joined the Union, three women are on the Council, and their advice has been helpful in many cases. Efforts have recently been made to induce the Union to make some concession to members of the British Medical Association, but the Council had declined to make any differential treatment. Both the Union and the London and Counties Medical Protection Society felt that they were mutually concerned in maintaining complete independence, and with a view to the promotion of good feeling, and, where necessary, coöperation, a standing joint committee, consisting of representatives of each society, had been constituted and would meet at regular intervals.

The transfer to the new offices in Bedford-square has been effected without any interruption to work and the change is much appreciated. In view of the higher costs of litigation, the Council has thought it prudent to raise the amount of the insurance indemnity after Jan. 1st next to £3000, the improved financial position of the Union enabling the Council to provide the additional cover without any increase in the annual subscription to the Union. The President specially pointed out that charges of negligence and malpraxis against medical practitioners were no less frequent to-day than formerly. By far the greater number of the allegations which doctors were called upon to meet were a mere pretext for evading the payment of professional accounts. He could not conceive how anyone engaged in active practice could be so foolish as to refuse to avail himself of the protection which an organisation such as the Medical Defence Union afforded. He regarded membership of a Defence Society as equally important with registration as a medical practitioner, and was glad to find that the newly qualified were joining the Union in increasing numbers.

The annual report of the Council and the statement of accounts were adopted. Dr. M. Hallwright, Dr. W. Rigden, and Dr. H. Robinson were re-elected members of the Council. On the recommendation of the Council the following resolution was unanimously adopted :—

> That the Council of the Medical Defence Union, having full discretion under the Articles of Association as to the cases which it shall undertake on behalf of a member, shall have full discretion in any case in connexion with divorce proceedings to withhold or partially withhold the indemnity insurance afforded to members in respect of damages and costs of the other side which may be awarded against them.

A hearty vote of thanks was accorded to the President and Council for their services during the past year.

The Council, at its meeting on Oct. 4th, unanimously appointed Mr. Walter G. Spencer President of the Union for the ensuing year.

SOCIOLOGICAL SOCIETY.—A course of six lectures on the Bearing of Psycho-Analysis upon Sociological Problems will be held at Caxton Hall, on consecutive Tuesdays, at 8.30 P.M. The introductory lecture was delivered by Dr. Ernest Jones on Oct. 9th. Subsequent lectures will be given by Dr. James Glover, Mr. J. C. Flugel, Dr. M. D. Eder, Miss Barbara Low, and Miss E. Sharpe. Further particulars may be obtained from the Secretary, Psycho-Analytical Lecture-Course, Leplay House, 65, Belgrave-road, Victoria, London, S.W. 1.

HUNTERIAN SOCIETY.—The programme of the Society for the session 1923–24 is briefly as follows : Oct. 22nd, dinner meeting at Simpson's Restaurant, Cheapside ; presidential address by Sir H. E. Bruce Bruce-Porter on the Pitfalls of Medical Practice. Nov. 19th, at Cutler's Hall, discussion on Medicine and Letters, opened by Mr. W. B. Maxwell. Dec. 17th, dinner meeting at Simpson's Restaurant, Cheapside ; discussion on the Influence of Ductless Glands in Infancy, Middle, and Old Age, by Drs. Langdon Brown, J. H. Thursfield, Leonard Williams, and Crichton Miller. Jan. 14th, at the Mansion House, Hunterian lecture on Infections of the Urinary Tract due to the *B. coli communis*, by Sir John Thomson-Walker. Feb. 12th, annual dinner at the Langham Hotel. March 3rd, at the Mansion House, Hunterian oration, Changing Standpoints in Cardiac Medicines, by Sir Sydney Russell-Wells. March 24th, dinner meeting; paper on Rheumatics, by Dr. F. J. Poynton. Aprll 14th, annual general meeting.

HEALTH WEEK.—The Health Week Committee appointed by the Royal Sanitary Institute have been conducting an extensive campaign, which finished this week, with the object of impressing on the public the need of an intelligent understanding of the principles of health and hygiene in ameliorating the distresses of our time. The ordinary man knows in his heart that unless our civilisation keeps us healthy it is of no use, and that the one great cause of disease is ignorance. As knowledge has spread during the last 50 years, so has the expectation of life increased, but as yet the national health and physique is far from the ideal. It is believed that the death-rate of the country could be reduced by 40 per cent. if the knowledge now existing among well-informed men in the medical profession were actually applied in a reasonable way and to a reasonable extent. The Public Health Committee of the West Riding County Council, under the direction of the county medical officer, have been conducting a vigorous health propaganda among school-children. Addresses have been delivered in the schools by some 142 medical practitioners, who have consented to give their services voluntarily. Leaflets of an attractive and interesting nature have been widely distributed among the scholars to encourage habits of cleanliness, and to create an interest in the care of the body.

A paragraph from the "Scholar's Health Creed" runs: "I believe that my individual and personal effort is even more necessary than the help of the sanitary authorities or the medical officer of health in producing a high standard of health in the community, for I am indeed 'my brother's keeper.'" The press and the pulpit have coöperated in the work, while a series of 24 lectures has been arranged by the county council for the coming winter.

London Dermatological Society.—A general meeting of the Society will be held at 4.30 p.m. on Oct. 16th at St. John's Hospital, 49, Leicester-square, W.C. At 5.15 p.m. Dr. A. Knyvett Gordon will read a paper on the Clinical Value of Biochemical Tests in Dermatology.

Institute of Hygiene.—A series of lectures upon Food and Diet will be delivered at the Institute of Hygiene on Tuesdays, at 3.30 p.m., beginning on Oct. 16th, when Mr. Grant Ramsay will lecture on Foods, Feeding, and Efficiency.

Donations and Bequests.—Colonel Hubert Alfred Johnson, of Allestree, Derbyshire, and Bradford Iron Works, Manchester, who for some years commanded the 4th Manchesters and who saw service during the war, bequeathed £500 each to the Derbyshire Royal Infirmary, the Derbyshire Hospital for Sick Children, the National Society for the Prevention of Cruelty to Children, the Royal Society for the Prevention of Cruelty to Animals, the Ancoats Hospital, and Ardwick and Ancoats Dispensary, Manchester.

Fellowship of Medicine and Post-Graduate Medical Association.—A special intensive course in Proctology will be given at St. Mark's Hospital, City-road, from Oct. 15th to 27th, and will include clinical lectures and demonstrations in the wards and out-patient department each day by the members of the staff. A short course in Dermatology will also be held at the Hospital for Diseases of the Skin, Blackfriars, from Oct. 29th to Nov. 10th, and the next fortnight's "refresher" course in General Medicine and Surgery will be given by the Royal Northern Hospital in conjunction with the Central London Ophthalmic Hospital, the North-Eastern Fever Hospital, and the Royal Chest Hospital from Nov. 5th to 17th. There will also be further special courses during November on Children's Diseases at the Children's Clinic, Western General Dispensary; Gynæcology at Chelsea Hospital for Women; Ophthalmology at the Royal Westminster Ophthalmic Hospital; Psychological Medicine at the Maudsley Hospital; and on Venereal Disease at the London Lock Hospitals. Full particulars and copies of the syllabus of the above courses can be obtained from the Secretary to the Fellowship of Medicine, at 1, Wimpole-street, W. 1. As in some cases the number attending the courses is limited, early application should be made.

Medical Sickness, Annuity, and Life Assurance Society.—The annual report of the Society for the year ending June 30th, 1923, states that the number of sickness and accident fund policies issued was 353 for annual premiums of £4504. Sickness claims paid amounted to £19,072. The total of the fund at close of the period was £245,336. Life assurance policies numbered 119, assuring £78,450 less re-assurances of £500, net £77,950, for net annual premiums of £2901 and single premiums of £219. Claims paid totalled £1434. The total premium income of the Society amounted to £47,043. The expenses of administration were £7158, being 15·4 per cent. of the premium income. The rate of interest earned was £4 13*s.* 8*d.* per cent. gross, and £3 14*s.* 6*d.* per cent. after deduction of tax. The two funds have increased by £8486, and amount, after transferring £3000 to the reserve fund and £2000 to the staff pension fund, in accordance with the resolution passed at the annual meeting, Oct. 2nd, 1922, to £349,230.

Newcastle-upon-Tyne and Northern Counties Medical Society.—The first meeting of the session was held in the Royal Victoria Infirmary on Oct. 4th. Dr. R. Esmond Moyes, the President, was in the chair, and about 100 members were present. A large number of medical and surgical cases were demonstrated by the following members: Prof. W. E. Hume, Drs. George Hall, G. A. Berkeley Cole, S. Whateley Davidson, J. C. Spence, Prof. H. Brunton Angus, Messrs. Hamilton Drummond, W. A. Hewitson, H. Harvey Evers. A series of pathological specimens from the museum of the University of Durham College of Medicine was arranged by Mr. W. E. M. Wardill, the curator. The Society meets monthly during the winter session, and in addition to the ordinary meetings two clinical and pathological meetings have been arranged for the convenience of country members, at 4.30 p.m., on Oct. 24th and Jan. 23rd, 1924. The annual address and dinner will take place on Dec. 6th. On Feb. 7th, 1924, an address will be delivered by Dr. Hugh Thursfield, London, and on March 6th a discussion will be opened by Dr. Leith Murray, Liverpool, on Cæsarean Section, its History, Indications, and Limitations.

Medical Diary.

Information to be included in this column should reach in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Oct. 16th.

GENERAL MEETING OF FELLOWS: at 5 p.m.
Ballot for election to the Fellowship. (Names already circulated.)

PATHOLOGY: at 8.30 p.m.
Papers:
Dr. James Young: Further Observations on the Ætiology of Malignant Disease and the Leukæmic Phenomena.
Dr. E. H. Kettle: Experiments with "Defatted" Tubercle Antigen.
Dr. J. Freeman: Pollen Antigen prepared by Dreyer's Method.
Dr. E. E. Atkin: Cultural Characteristics of the Different Types of Meningococci.

Wednesday, Oct. 17th.

HISTORY OF MEDICINE: at 5 p.m.
Paper: Dom Louis Gougaud, O.S.B.: Phlebotomy in the Monasteries.

Thursday, Oct. 18th.

DERMATOLOGY: at 5 p.m. (Cases at 4.30 p.m.)
Cases:
Dr. H. MacCormac: Erythematous Lupus with Hypodermic Nodes.
Dr. H. W. Barber: (1) Prurigo Nodularis; (2) Macular Atrophy; (3) Persistent Streptococcal Impetigo.
At 8.30 p.m., Special Evening Meeting.
Paper:
Dr. J. A. Fordyce (Columbia University): Results of Treatment in Syphilis of the Nervous System.

Friday, Oct. 19th.

ELECTRO-THERAPEUTICS: at 8.30 p.m.
Presidential Address:
Dr. W. J. Turrell: Electrical Energy as a Curative Agent

THE ROYAL SOCIETY OF TROPICAL MEDICINE AN HYGIENE, 11, Chandos-street, Cavendish-square, W.
Thursday, Oct. 18th.—8.15 p.m., Opening Meeting of th Session, Surgeon Rear-Admiral Sir Percy Bassett Smith, K.C.B., C.M.G., President, will deliver hi inaugural address. The meeting will be preceded by Demonstration at 7.45 p.m., of the Development of th Malaria Parasite in the Mosquito.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

POST-GRADUATE COLLEGE, WEST LONDON HOSPITAL Hammersmith, W.
Monday, Oct. 15th.—10 a.m., Mr. Maingot: Surgica Pathology. 12 noon, Mr. Simmonds: Applied Anatomy 2 p.m., Mr. Simson: Diseases of Women.
Tuesday.—10 a.m., Mr. Steadman: Dental Department 12 noon, Dr. Burrell: Chest Cases. 2.30 p.m., Mr Tyrrell Gray: Surgical Wards.
Wednesday.—10 a.m., Dr. Saunders: Medical Diseases o Children. 12.15 p.m., Dr. Burnford: Medical Pathology 2 p.m., Dr. Pernet: Skin Department.
Thursday.—10 a.m., Dr. Grainger Stewart: Neurologica Department. 12 noon, Mr. Simmonds: Demonstratio of Fractures. 2 p.m., Mr. MacDonald: Genito-Urinar Department.
Friday.—11 a.m., Dr. McDougal: Electrical Department 12 noon, Dr. Endean: Venereal Diseases. 2 p.m. Mr. Sinclair: Surgical Out-patients.
Saturday.—10 a.m., Dr. Saunders: Medical Diseases o Children. 10 a.m., Dr. Burnford: Medical Ward 10 a.m., Mr. Banks-Davis: Operations on the Throa Nose, and Ear.
Daily, 10 a.m. to 6 p.m., Saturday 10 a.m. to 1 p.m., I patients, Out-patients, Operations, Special Depar ments.

NATIONAL HOSPITAL FOR DISEASES OF THE HEAR Westmoreland-street, Marylebone, W. 1.
(Special Two Weeks' Intensive Course in Cardiology. Mornin 10 and 11.15 a.m.; afternoons 2 and 3 p.m. Saturday in the forenoon only.)
Monday, Oct. 15th.—Dr. B. T. Parsons-Smith: T Anatomy of the Heart. Dr. J. Strickland Goodal X Ray Examination of the Heart. Dr. R. O. Moon Ward Demonstration. Dr. J. Strickland Goodal Out-patients.
Tuesday.—Dr. P. Hamill: The Physiology of the Circula tion. Sir S. Russell-Wells: Sphygmomanometers a Arteriometers. Dr. F. W. Price: Ward Demonstr tion. Sir S. Russell-Wells: Out-patients.
Wednesday.—Dr. John Parkinson: The Uses of t Polygraph. Dr. F. W. Price: Cardiac Arrhythmia Dr. H. B. Weir: Pathological Demonstration. D R. O. Moon: Out-patients.
Thursday.—Dr. John Parkinson: The Uses of the Pol graph. Sir S. Russell-Wells: Angina Pectoris. D J. Strickland Goodall: Ward Demonstration. D F. W. Price: Out-patients.

FRIDAY.—Dr. B. T. Parsons-Smith: The Electro-Cardiograph. Dr. R. O. Moon: Mitral Stenosis. Dr. John Parkinson: Ward Demonstration. Dr. John Parkinson: Out-patients.

SATURDAY.—Dr. P. Hamill: Ward Demonstration.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: OCTOBER–NOVEMBER, 1923.

CLINICAL LECTURES AND DEMONSTRATIONS.

MONDAY, Oct. 15th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Subacute Combined Degeneration: Dr. James Taylor.

TUESDAY, Oct. 16th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Disseminated Sclerosis and its Treatment: Dr. Risien Russell.

THURSDAY, Oct. 18th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Magnus and de Kleijn Reflexes in Man: Dr. Walshe.

FRIDAY, Oct. 19th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Myelitis: Dr. Collier.

COURSE OF LECTURES AND DEMONSTRATIONS ON NEURO-PATHOLOGY.

MONDAY, Oct. 15th.—12 noon, Cerebro-spinal Fluid Pathology: Dr. J. Godwin Greenfield.

A COURSE of LECTURES on the ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM will commence on Oct. 16th.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

The fee for the Course, including Pathology, is £5 5*s*. The fee for the Anatomy and Physiology Lectures will be £3 3*s*., but this Course will only be given if six or more entries are received. If taken in conjunction with the Clinical and Pathological Courses, an inclusive fee of £7 7*s*. will be charged. Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course.

C. M. HINDS HOWELL, Dean of Medical School.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Oct. 18th.—4 P.M., Dr. Paterson: Convulsions in Infancy and Childhood.

LIVERPOOL UNIVERSITY CLINICAL SCHOOL. (At 3.30 P.M. each day.)

MONDAY, Oct. 15th (at the Hospital for Women).

TUESDAY (at the Maternity Hospital).—Dr. Willett: Primigravida.

WEDNESDAY (at the St. Paul's Eye Hospital).—Mr. Stevenson: Ophthalmia Neonatorum.

THURSDAY (at the St. George's Hospital).

FRIDAY (at the Eye and Ear Infirmary).—No lecture.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, Oct. 16th.—4.15 P.M., Dr. W. Dyson: Erythematous and Bullous Eruptions of the Skin.

FRIDAY.—4.15 P.M., Dr. F. Craven Moore: The Modern Conception and Investigation of Dyspepsia.

SALFORD ROYAL HOSPITAL.

(Special Course on Surgical Tuberculosis.)

THURSDAY, Oct. 18th.—4.30 P.M., Mr. G. Wright: The Surgery of Pulmonary Tuberculosis.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

MONDAY, Oct. 15th.—5 P.M., Dr. A. Blackhall-Morison: The Progress of Neurology, Psychology, and Psychiatry during the Century since the Foundation of the Lectureship.

TUESDAY.—Second Lecture.

WEDNESDAY.—Third Lecture.

Appointments.

DILLON, F., M.D. Edin., has been appointed Medical Superintendent of Northumberland House Private Mental Hospital.

HURRELL, G., M.B., B.S., D.P.H., B.Hy. Durh., Assistant R.M.O., City Hospital, Walker Gate, Newcastle-on-Tyne.

Manchester, Whitworth-street West Hospital: **BAILEY, K. V.**, M.B., Ch.B. Manch., **GERAGHTY, W.**, M.B., Ch.B. Manch., **BACON, W. B.**, and **FILDES, W. E.**, House Surgeons. High-street Hospital: **HULME, J. W.**, M.R.C.S., L.R.C.P. Lond., and **BEGG, ELSIE C.**, M.B., Ch.B. Manch., House Surgeons. St. Mary's Hospitals: **GRANT, MARJORIE A.**, Assistant Medical Officer for Children Out-patients.

Certifying Surgeons under the Factory and Workshop Acts: **IVATTS, E. R.**, M.R.C.S., L.R.C.P. Lond. (Cerrig-y-Druidion, Denbigh); **COURTS, A. C. S.**, M.D., B.S. Lond. (Staveley, Derby).

Vacancies.

For further information refer to the advertisement columns.

Ashton-under-Lyne District Infirmary.—H.S. £150.

Bethlem Hospital, Lambeth-road, S.E.—Two Res. H.P.'s.

Birmingham, Queen's Hospital.—Path. £100.

Bradford Royal Infirmary.—Hon. Asst. S.

Cape Town University.—Wernher-Beit Prof. of Bacteriology.

Cardiff, King Edward VII. Welsh National Memorial Association.—Second Asst. R.M.O. £250.

City of London Hospital for Diseases of the Heart, Victoria Park, E.—H.P. £125.

City of London Mental Hospital, near Dartford, Kent.—Second Asst. M.O. £350.

Denbighshire County Council.—Asst. M.O.H. £600.

Dumfries, Crichton Royal.—Asst. P. £350.

Durham County Council Education Dept.—Asst. School M.O. £600.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—R.M.O. £200. H.S. £125. Radiologist. £100. Dermatologist.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Asst. Radiologist. £50 to £100.

Gloucestershire Royal Infirmary.—Hon. Anæsth. Two Hon. Dental Surgeons.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. Also Res. M.O. £500.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. and H.P. £150 and £100 respectively.

Italian Hospital, Queen-square, W.C.—Hon. Ophth. S.

Leeds Public Dispensary.—Sen. Res. M.O. £200.

Leicester Royal Infirmary.—H.S. £150.

London County Mental Hospital Service.—Seventh Asst. M.O. £432.

Manchester Hospital for Consumption and Diseases of the Throat.—Hon. Asst. Phys.

Manchester Royal Infirmary.—Female Asst. Res. M.O. £100.

Manchester, St. Mary's Hospitals.—H.S. £50.

Metropolitan Hospital, Kingsland-road, E.—Sen. H.P. and H.S., Jun. H.P., and three Jun. H.S.'s. Each £100.

National Dental Hospital, Great Portland-street, W.—Hon. Anæsthetist.

Poplar Parish.—Dist. M.O. £200.

Portsmouth Workhouse Infirmary, &c.—Second Asst. Res. M.O. £425.

Prince of Wales's General Hospital, Tottenham, N.—Hon. Asst. S. to Ear, Nose, and Throat Dept.

Richmond Royal Hospital, Surrey.—Asst. H.S. £100.

Royal London Ophthalmic Hospital, City-road, E.C.—Sen. H.S. £150.

Royal National Orthopædic Hospital, 234, Great Portland-street, W.—Clin. Assts. £105.

Royal Northern Hospital, Holloway, N.—H.P. and H.S. Each £75.

St. Helens County Borough.—Asst. M.O. £600. Also Asst. M.O.H. £450.

St. Mary, Islington, Infirmary, Highgate Hill.—Asst. Med. Supt. £500.

St. Pancras Hospital, Pancras-road, N.W.—Female Asst. M.O. £350.

Sheffield Union Hospital.—Res. Asst. M.O. £250.

Staffordshire General Infirmary, Stafford.—H.S. £200.

Talgarth, Breconshire, Mid Wales Counties Mental Hospital.—Asst. M.O. £350.

University College Hospital, Gower-street, W.C.—Hon. Asst. in Ear, Nose, and Throat Department.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—Temp. Physician to Out-patients.

West Hartlepool, Cameron Hospital.—H.S. £200.

York County Hospital.—Res. M.O. £150.

Births, Marriages, and Deaths.

BIRTHS.

HOLMES.—On Oct. 5th, at Wimpole-street, W., the wife of Gordon Holmes, C.M.G., M.D., of a daughter.

JEX-BLAKE.—On Sept. 13th, at Kyuna, Nairobi, Kenya Colony, to Lady Muriel and Dr. A. J. Jex-Blake—a daughter.

PENDERED.—On Oct. 1st, at West End, Hants, the wife of J. H. Pendered, M.D., F.R.C.S., Southampton, of a son.

STANLEY.—On Oct. 5th, at Rue des Belles Feuilles, Paris, the wife of E. Gerald Stanley, M.S., F.R.C.S., M.D., of a daughter.

MARRIAGES.

GALBRAITH—BOWEN-JONES.—On Oct. 1st, at St. George's, Beckenham, Captain Douglas Hugh Aird Galbraith, *M.C.*, M.R.C.S., L.R.C.P., to Hannah Bowen-Jones, R.R.C., only daughter of Mrs. Bowen-Jones, of Conwil, Carmarthenshire.

LITTLE—FORRER.—On Oct. 3rd, at St. Barnabas Church, Kensington, Captain Joseph Pearson Little, R.A.M.C., to Alice Cleopatra, younger daughter of Mr. and Mrs. Jefferson Forrer, of Alexandria, and niece of the late Henry Forrer, Liverpool.

PATERSON—MURPHY.—On Sept. 27th, at the British Consulate, Cairo, Dr. T. W. S. Paterson, M.A., M.B. Camb., Barrister-at-Law, Middle Temple, to Mrs. E. H. Murphy.

DEATHS.

KEEN.—On Oct. 2nd, at St. Leonards-on-Sea, William Keen, M.D., of Oakley-street, Chelsea, S.W.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE HISTORY OF A SURGICAL SOCIETY.

In 1872 Bernard v. Langenbeck, Gustav Simon, and Richard Volkmann conceived the idea of forming a surgical society with an annual congress of three to four days' duration. The idea was announced to a number of German surgeons by means of a circular letter, with the result that in April, 1872, the first meeting was held under the presidency of v. Langenbeck, a post which he held with distinction until 1886, a year before his death. Victor v. Bruns was elected as vice-president, Volkmann and Gurlt as secretaries, and Friedrich Trendelenburg as treasurer. Dr. Trendelenburg has now collected,[1] summarised, and edited the reports of the meetings of this Deutsche Gesellschaft für Chirurgie during the first 25 years of its existence. Personal reminiscences of the parts played by himself and others add greatly to the interest of the book. Baum, Bardeleben, Billroth, and Simon formed the first committee. Although it was to Simon that the credit was given of originating the idea, and it was to him and his untiring efforts that the success of the scheme was due, his inability to speak publicly, "schwätzen" as he called it, prevented him from taking so prominent a place at the meetings as Langenbeck or Volkmann.

By dividing the subject-matter into the obvious headings, Dr. Trendelenburg traces for us the development of surgical thought and practice in its various branches during the first 25 years following the formation of the society, and we are shown the phases and vicissitudes through which new scientific ideas fought their way to acceptance or rejection. The account of the views that were held on septic wounds and compound fractures in military and civil practice forms fascinating reading. "Everyone is agreed," said Pirogoff, "that pus formation in gunshot wounds is unavoidable." If a gunshot fracture healed with only slight suppuration, without extrusion of a sequestrum, it was assumed that the case was one of simple fracture without splintering, for as Simon maintained, if a compound fracture was present, infection invariably took place and led to death in a few weeks. The sensation caused by Lister's theories and the resistance to them, the advent of antiseptics and the antagonism to these, and the occurrence of iodoform poisoning, are all reflected in the discussions held by the society. The debate in 1892 on local versus general anæsthesia, or rather the abrupt cessation of the debate must have long remained vivid in the minds of all those who were present. Schleich opened the discussion advocating strongly on humanitarian and moral grounds the universal use of local anæsthesia. When he ceased speaking Bardeleben jumped to his feet, "his clear-cut face flushed with anger, surrounded by his waving white beard," and with an excited voice said, "Gentlemen, we do not vote in our society, but when anything is said such as the last sentence of the last speaker, we are at liberty to speak out our opinion. . . . I ask those who are convinced of the truth of what the last speaker has said to hold up their hands. Gentlemen, no hands are raised. . . . Will those who wish for a discussion hold up their hands. No hand is raised. There is, therefore, no discussion." Compare this position with that held to-day, when in most of the continental hospitals 70–80 per cent. of all operations are carried out under local anæsthesia.

The history of blood transfusion well repays perusal. The blood was thought at one time to influence the psychology of the individual, and Elsholz in 1667 suggested that transfusion of the blood from a choleric personality might correct the temperament of a phlegmatic, and that an unhappily married couple might be brought into harmony by reciprocal blood transfusion! The chapter on the surgery of the gall-bladder illustrates how gradually surgery has advanced since that time. Cholecystectomy versus cholecystotomy was discussed as freely then as now, and who can say when the questions will be settled? But we have progressed since the days of humeral pathology, when hæmorrhage from the rectum due to hæmorrhoids was looked upon as similar to menstruation—a "charitable gift of nature." To those interested in the history of surgery this book should appeal.

THE PROTECTION OF THE GAS CONSUMER.

On Oct. 1st was published the last of three special supplements to the *Manchester Guardian*, which between them cover all aspects of the gas industry. The first issue, which appeared on Sept. 10th, included an historical survey and a section devoted to coal and coal conservation; the second issue, dated Sept. 24th, was devoted to manufacture and distribution of gas, and smoke abatement and public health. The third issue relates to the practical application of gas in modern civilisation, and to the economics and organisation of the industry; it also contains a brief summary of "the four chief safeguards by which gas consumers are protected against possible underhand dealing." These are as follows:—

1. *Parliament.*—Suppliers of gas are not at liberty to change the quality of their gas except in accordance with Parliamentary statutes; nor may they alter the calorific value of the gas without adjusting appliances, if such adjustment be necessary to enable consumers to extract a maximum efficiency from the altered quality of the gas. (Such adjustment is usually unnecessary for altered calorific values within comparatively narrow limits—e.g., a change from 450 to 475, or from 475 to 500 British thermal units per cubic foot.) A sliding scale admits of higher dividends only when gas is cheapened, and prevents the shareholder in a gas company from profiting at the expense of the consumer.

2. *Board of Trade.*—No undertaking can benefit by the Gas Regulation Act (1920) except by receiving an order from the Board of Trade; and such an order is only issued after the Board is satisfied that its terms are in the consumer's interest.

3. *Official Testing.*—The calorific value of gas is carefully tested, frequently and without warning, by an officially appointed neutral party. The consumer is, therefore, paying only for heat supplied, because (*a*) a public authority certifies the maintenance of the declared calorific value of the gas; (*b*) his meter, tested and guaranteed by a neutral party, records the number of feet consumed; and (*c*) where gas is sold on the therm basis a simple calculation shows the number of therms contained in the number of cubic feet consumed—namely, multiplication of the number of cubic feet by the declared heating value, and division of the results by 100,000.

4. *Local Authority.*—Consumers, if dissatisfied, have the right, by Act of Parliament, to go to their local authority and demand that the Board of Trade be asked to revise the local standards.

THE MEDICAL WHO'S WHO.

This publication was suspended in 1918 on the death of its late editor. Begun in 1912 as a very modest volume of 300 pages, it grew through successive editions, all of which are out of print, to a substantial volume, and the Grafton Publishing Co., Ltd., Chichester House, Chancery-lane, W.C. 2, have now acquired the copyright, and will reissue the work on a revised plan. All registered practitioners will shortly receive a form to be filled up, which we are informed has been submitted to the General Medical Council. The new book of reference aims at blending the good features of the Medical Directory with those of "Who's Who," and if this is successfully accomplished the book should prove of value to the practitioner, and be of general use. The editor of the "Medical Who's Who" is appealing for an early return of the forms.

AN IMPROVED HAIR-BRUSH.

The advantages of a hair-brush which can be cleaned and sterilised at any moment by passing it through a spirit flame, by immersing it in boiling water, or by using disinfectants, are obvious, and these advantages are claimed for the Sindix All-metal Hair-Brush. It is made in two shapes, the military, and the ordinary handled form for the convenience of ladies. The "bristles" are made of fine-drawn, non-rusting wire, and the body of the brush is of aluminium and perforated with openings so that the cleansing or disinfecting fluid can pass freely through all parts of it. The makers are Sindix, Ltd., 5, John-street, Adelphi, London. W.C., and the price is 12*s.* 6*d.*

A BEE-STING ON THE UVULA.

An unusual accident occurring to a motor cyclist is recorded by Dr. C. W. Geiger and Dr. J. H. Roth in the *Journal* of the American Medical Association of August 25th. The victim was a youth into whose open mouth a bee flew while he was travelling presumably at some pace. After several attempts the insect was dislodged. Violent vomiting followed and attempts to gargle caused the pain to be worse. Six hours after the accident the patient had slight difficulty in speech, and considerable difficulty in swallowing. Examination of the pharynx showed extreme œdema of the uvula, which was about the size of a man's thumb, and of the pillars on the right side. Cocaine was applied to render examination possible; at the junction of the anterior pillar and the uvula the stinger of the bee was found and removed, silver nitrate (10 per cent.) was applied as an astringent; the patient was given a gargle of saturated solution of sodium bicarbonate to be used frequently and was soon relieved.

The Harveian Oration

ON

THE WISDOM OF THE BODY.

)elivered before the Royal College of Physicians of London on St. Luke's Day, 1923,

3Y ERNEST H. STARLING, C.M.G., M.D. LOND., SC.D. (HON.) CAMB. AND DUB., M.D. (HON.) BRESLAU, DOCT. (HON.) STRASBURG, F.R.S.,
FOULERTON RESEARCH PROFESSOR OF THE ROYAL SOCIETY; FELLOW OF THE COLLEGE.

> "Who hath put wisdom in the inward parts?
> or who hath given understanding to the heart?"

MR. PRESIDENT AND FELLOWS OF THE COLLEGE,—t is customary and right in this our annual oration o begin by calling to mind the work of the founder imself, and especially the great discovery of the irculation of the blood, which represents the beginning and the foundation of all that we know in hysiology and medicine. Harvey's treatise on "The Iotion of the Heart" is throughout so modern in pirit, so akin in conception and treatment to records f research of the present day, that we may easily ail to appreciate the stupendous advance in human hysiology that it embodies, and may wonder that e have had to wait so long for the full fruition of Iarvey's discovery. But it must be remembered hat the ordered knowledge of the world around us, hether living or dead, which we call science, forms connected whole; and though, as its line advances, brilliant discovery may push one part of the line in dvance of the rest, such an outpost must remain nore or less in the air and incapable of further dvance until the whole line has moved up to its upport. We now know that many of the problems aised by Harvey, with the promise to himself and is readers of further consideration at a later date, epended for their solution on the progress of other ranches of human knowledge. And that is why o-day in our minds and memories we are reckoning mong our saints, not only the distinguished line of ellows of the College, but also men such as Boyle, Iayow, Hales, Cavendish, Lavoisier, Bernard, Pasteur, nd a host of others, who were only in spirit ur colleagues, and most of whom were not even tudents of medicine. Indeed, we might say that, luring the 200 years succeeding Harvey's work, the vhole scientific world has been travailing in order hat medicine might be born. Thus it is that our cience has had to wait until our own days for the ttainment of those ends which Harvey had in mind n his dream of the results of his discovery: "Finally, eflecting on every part of medicine, physiology, athology, semeiotics, therapeutics, when I see how nany questions can be answered, how many doubts esolved, how much obscurity illustrated, by the ruth we have declared, the light we have made to hine, I see a field of such vast extent in which I night proceed so far, and expatiate so widely, that his my tractate would not only swell out into a olume, which was beyond my purpose, but my whole fe, perchance, would not suffice for its completion."

In the new light shed by his great discovery, he robably failed to appreciate the extent of the dark hadows cast by the great clouds of ignorance which ad still to be dispersed. But the advance of knowedge, though slow at first, has progressed with ever ccelerating speed. When I compare our present nowledge of the workings of the body, and our owers of interfering with and of controlling those vorkings for the benefit of humanity, with the gnorance and despairing impotence of my student ays, I feel that I have had the good fortune to see he sun rise on a darkened world, and that the life of ny contemporaries has coincided, not with a renaisance, but with a new birth of man's powers over his nvironment and his destinies unparalleled in the vhole history of mankind. Not but there is still nuch to be learned: the ocean of the unknown still stretches far and wide in front of us, but for its exploration we have the light of day to guide us; we know the directions in which we would sail, and every day, by the coöperation of all branches of science, our means of conveyance are becoming more swift and sure. Only labour is required to extend almost without limit our understanding of the human body and our control of its fate.

HARVEY'S GREATEST GIFT TO THE WORLD.

Great as was the gift which Harvey gave to us in his discovery of the circulation of the blood, greater still was the method he taught us of formulating and solving the problems which we continually encounter in our endeavours to control disease. For countless ages mankind had learned slowly and painfully by experience. The more observant had from time to time noticed certain recurring sequences in the infinity of fortuitous phenomena continually presented to them, and as a result man had by slow degrees improved his lot and his powers over the forces of Nature. But how slow was the rate of progress. There is no evidence that the age-long duration of the period during which man had only sticks and stones to defend himself and to procure his food, the long delay in the discovery of the working of bronze and later of iron, are to be ascribed to any mental inferiority of those men as compared with those of the present day. What was lacking was the method. Mankind had advanced by fits and starts as the result of discoveries which were probably accidental, and these discoveries spread gradually along the lines of commerce and culture by imitation and the implicit copying of ritual. But with the realisation of the possibilities of the method of experiment—i.e., the creation and repetition of a chosen experience under controlled conditions, such as we find in its full development in Harvey's treatise—man came almost at a bound into the full use of the brain capacities which he had evolved during a long struggle for existence against the warring forces of an inclement nature.

It is true that the ultimate goal and the biological justification of science is the improvement of human conditions. But for the full and untrammelled exploitation of the advantages of the experimental method, it is essential that mere material advance shall not be the target of our ambition. This great secret of success in science was fully realised by Harvey when he enjoined us to search out, not the causes and cure of disease, but "the secrets of Nature, by experiment." This implies that we are to give free scope to the spirit of curiosity, with some measure of which every man, at any rate in his youth, is endowed. We ourselves are but part of the order of Nature, and all knowledge therefore is contributory to the science of medicine.

THE WORK OF THE HEART.

If this was the spirit that actuated Harvey, it is evident that his whole life would not have sufficed for the completion of the work opened up to him by his great discovery. Under its light he could see many summits to be attained and the beginnings of paths which must be followed. But long and arduous search was necessary before these paths could be traced out in their entirety. Thus the determination of the output of blood from the heart and the cause of its variations evidently seemed to Harvey a problem whose solution was ready to hand. He says: "The actual quantity of blood expelled at each stroke of the heart, and the circumstances under which it is either greater or less than ordinary, I leave for particular determination afterwards from numerous observations which I have made on the subject. Meantime, this much I know, and would here proclaim to all—that the blood is transfused at one time in larger, at another in smaller quantity; and that the circuit of the blood is accomplished, now more rapidly, now more slowly, according to the temperament, age, &c., of the individual, to external and internal circumstances, to naturals and non-naturals—sleep, rest, food, exercise, affections of the mind, and the like."

But many years had to elapse before we could give a quantitative expression both to the amount of blood expelled under normal conditions and to its variations, and explain the manner in which these variations are brought about. The Rev. Stephen Hales, second only to Harvey as an experimental physiologist, has only calculations based on measurements of the dead organ. The determination of the output in the living animal was first made in our own times, and it is only within the last ten years that methods have become available which reveal in man himself the quantity of blood leaving the heart in each unit of time, and therewith enable us to estimate the total work of this organ. Such methods have been devised by Krogh and by Haldane. If we accept the results of the former, we may say that in a normal man at rest each cavity of the heart expels about four litres per minute. During violent exercise when, as we know, the requirements of the body for oxygen may be increased tenfold, this quantity rises to 24 or even to over 30 litres (3 gallons) per minute. These figures convey only imperfectly the enormous rush of blood which is being effected by the heart under these conditions. An ordinary laboratory tap will deliver nothing like 30 litres per minute; to obtain this amount it is necessary to have recourse to a large tap such as that which is supplied to a bath. It means that the whole blood must pass through the heart and round the body every ten seconds, and complete the circulation of the body six times in every minute. And it must be remembered that the heart is putting out this colossal amount of blood against an arterial pressure which is higher than normal, and which may amount to 150 to 180 mm. Hg as against the 100 to 110 mm. which is the ordinary systolic pressure in the arteries of a resting individual.

We see, therefore, that the heart has a marvellous power of adapting its work and its performance in accordance with the needs of the body as a whole, and is fully deserving of the feeling of respectful admiration which inspires Harvey to speak of it as "the sun of the microcosm," "the household divinity," "the foundation of life," "the source of all action."

ITS POWER OF ADAPTATION.

To search out the intimate character of this power of adaptation is a problem almost as enthralling in interest as the demonstration of the circulation itself. It is easy to show that the increased output of blood from the heart during exercise is simply an expression of an increased inflow into this organ, the heart being so constituted that under normal conditions it will send on into the arteries all the blood that flows into it from the veins. Harvey probably had some inkling of this power when, in speaking of the action of the auricles, he ascribes to them the property of exciting a stronger contraction on the part of the ventricles, comparing the latter to the tennis player who can strike more forcibly and further if he takes the ball on the rebound.

In the intact animal a large number of processes, nervous as well as chemical, are involved in the increased contraction of the heart during muscular exercise. By the action of the central nervous system and of other physiological processes involved, the strain thrown on the heart is minimised, so that it can effect the increased work with the greatest possible economy of effort. But the intimate character of this power of adaptation is fully displayed only when we cut away the protective mechanisms, which are normally shielding the last citadel of life, and study the reaction of this organ when it is entirely isolated from the central nervous system and is reduced to the condition of a muscular pump with valves, working rhythmically and steadily in virtue of its own automatic powers.

We can make a "heart lung preparation," in which, the lungs being retained in connexion with the heart, the blood passing through this organ is kept properly aerated. The systemic circulation is, however, replaced by a system of elastic tubes passing to a venous reservoir, in which we can vary at will the inflow of blood into the heart, the arterial pressure (and therewith the resistance to the expulsion of blood from the left ventricle), and the temperature of the blood supplying the heart, while we can measure the pressures at any moment of time in all the cavities of the heart as well as the changes in volume of this organ. In such a preparation we find that, within very wide limits, the output of blood corresponds exactly to the inflow. Whatever is supplied to the heart on the venous side is expelled by it on the arterial side. And again, within very wide limits, whatever is the resistance to be overcome in the arteries, so long as we keep the inflow of blood constant, the output of blood by the left ventricle remains unaltered whether the pressure in the aorta be 40 or 200 mm. Hg.

We know now that the energy for all vital movements is derived ultimately from the food, and in each tissue from the oxidation of the constituents either of the tissue or of the blood circulating through it. It is possible in such an isolated heart to measure its respiratory exchanges, and so determine the extent of the oxidative processes responsible for the energy of the heart's contraction. We then find that the amount of oxygen, taken in by the heart and converted for the most part into carbonic acid, is proportional to the amount of work that the heart is set to do. The isolated heart is like the whole man—the harder he works, the greater are his respiratory exchanges. I am accustomed to compare the heart with an ideal motor-car which, without action on the part of the driver, would automatically admit more petrol and air when the resistance to the movement of the car increases—as, for instance, in going up hill.

THE LAW OF THE HEART.

The heart has thus the power of automatically increasing the chemical changes and the energy evolved at each contraction, in proportion to the mechanical demands made upon it, behaving in this way almost like a sentient and intelligent creature. But the cause of this power must lie in the muscular walls of the heart itself, and a study of the conditions under which it occurs and the concomitant changes in the heart has revealed the secret of its wonderful power. The solution is simple. We find that in the isolated heart every increased resistance to its contraction is associated with an increased diastolic volume of the cavity or cavities, which have to overcome the resistance. Putting the matter in another way, we may say that the larger the diastolic volume of a given heart, the greater is the force of the contraction which immediately ensues. The energy of contraction is therefore a function of the diastolic volume of the heart. Dilatation of this organ is not merely a pathological phenomenon, but is the means by which the heart achieves its purpose, and maintains an activity which varies with the needs of the organism for more or less blood.

In this relation we find also the secret of the power of compensation, such as occurs in cases of valvular disease and has been always a puzzle to pathologists. Injury, for instance, to an aortic valve, with the production of regurgitation, causes increased filling of the left ventricle at the following diastole, since this receives blood not only in the ordinary way from the pulmonary veins and left auricle, but also by a reflux through the damaged valve. The dilatation evokes an immediate increase in the force of the contraction, so that within a few beats the left ventricle sends on into the aorta the total amount of blood flowing into it during the preceding diastole, and the aorta receives sufficient blood not only to supply the body, but to make up for the amount leaking back through the damaged valve. The same reasoning applies to the compensation which occurs for any valve lesion, whether it be in the nature of a leak or of a stenosis, increased filling or increased resistance; and in an otherwise healthy individual, constant increase in work has, as a secondary result, increased growth and hypertrophy of the cardiac muscle, so as to make it fit to meet the abnormally greater demands throughout the life of the individual.

You will remember that Harvey insists on the ssentially muscular nature of the heart. “ It was not ithout good grounds,” he says, “ that Hippocrates in is book “ De Corde ” entitles it a muscle ; as its ction is the same, so is its function—namely, to ontract and move something else.” Increasing ilatation of the heart means greater length of its uscular fibres, so that we can express the law of the eart as a relation between length and energy ; the onger the muscle fibre, the greater the energy of its ontraction. In this form we find that the law of the eart is that of all muscular tissue, whether voluntary r involuntary. The Swedish physiologist Blix showed any years ago that the energy evolved in the ontraction of a frog's muscle was proportional to its nitial length, and A. V. Hill has proved that this olds good for the heat production during activity nd therefore for the total chemical changes which re responsible for the contraction and recovery of the uscle. So that in searching after the cause of the eart's power of adaptation, we are brought into the egion of final causes, in which we associate function ith structure, and see in muscular contraction the xpression of molecular changes occurring at the urface of longitudinal fibrillæ. Thus we bring ogether in one formula the sum total of our experinces with regard to the nature of excitation itself, evelopment of mechanical energy, and the chemical, lectrical, and heat changes which accompany muscular ontraction. We are still far from a complete undertanding of these matters, and still farther from any ossibility of reconstructing a muscle fibre. But he path, so far as we can see along it, seems to lead o no impassable barrier, and to promise a complete escription of the acts of excitation and contraction s molecular events occurring at surfaces.

THE LIMITS OF ADAPTATION.

Is there any limit to this power of adaptation ? n skeletal muscle, increasing the length of the muscle bres leads to an augmentation of the energy changes f contraction, succeeded later by a diminution as he muscle becomes overstretched. In the healthy ammalian heart the limits are set by the strength of he muscle fibres themselves. Freed from the periardium the heart goes on increasing the strength of s contraction with increasing dilatation until the uscle fibres are actually ruptured, and when the eart finally fails we find its substance beset with æmorrhages. In the body this overstrain of the heart prevented by the tough fibrous sac of the periardium. When the demand on the heart is so great at the heart dilates to the limits of the pericardium ny further dilatation and resultant increased rength of beat becomes impossible ; the output therere falls off, and in the whole animal this diminished utput results in defective supply of blood to the uscles and brain, giving rise often to fainting, and t any rate enforcing complete rest. Further tivity of the animal becomes impossible and the eart is automatically given less work to do, so that can recover, unless the increased activity of the imal and of the heart is a necessary condition of e animal's continued survival, as in a fight to the ath. In this case, when the heart comes up against e pericardium. the fight is finished and the animal ccumbs. We find the same story in the terminal anges of heart disease, where the process of comnsation which I have described above becomes sufficient. Here again enforced rest may give time d opportunity for re-establishment of a sufficient rculation, but with advance of the fundamental orbid condition even complete rest becomes powerless relieve the heart ; the output falls off, the circulaon is insufficient for the needs of the tissues, and we t all the secondary results of failure of compensation -suppression of urinary secretion, water-logging of e body and malnutrition of all its organs, which her in the fatal termination.

During the last few years great advances have been ade in our knowledge of the causation of many of ese morbid conditions, and this increased knowledge has, as always, enhanced our powers of dealing with such cases, of staying the course of the disease or delaying its fatal issue. It is interesting to note that these advances are the direct outcome of researches made with the sole object of elucidating the intimate nature of muscular contraction. In his book Harvey remarks, “ Of these things we shall speak more opportunely when we come to speculate upon the final cause of this motion of the heart.” Such speculation at that time would have been in vain. It seems probable that he anticipated finding the solution in the study of the generation of animals, but we know now that to penetrate more deeply into the final cause of the action either of skeletal muscles or of the heart requires a physical and chemical knowledge which even now we are only beginning to attain. I would remind you that the string galvanometer, the employment of which has thrown so much light on the essential nature of disturbances in the heart rhythm, was invented by Einthoven with a view to study the electrical changes accompanying activity in any kind of tissue.

THE INHERENT RHYTHMIC POWER OF THE HEART.

In dealing with the origin of the rhythmic power of the heart, Harvey rightly ascribes it to the heart muscle itself, and brushes aside any suggestion that it is dependent on the nervous system, or the liver, or any other organ. His assurance on this point was due to his observation of the developing chick, in which the first sign of life was the pulsating spot of blood in the region where the heart was being formed. It is interesting to note that it is the same method —namely, the investigation of development—which has settled the question of the seat of the rhythmic power of the heart, and has revealed to us the origin and course of the rhythmically recurring wave of contraction in the heart of man. By means of a technique, first devised by Harrison in the United States, it is possible to cultivate living tissues outside the body in much the same way as we have learned to grow micro-organisms. Using great care to exclude infection we are able to transfer to plasma or salt solution on a glass slide fragments of tissue which, being kept warm, live and multiply. From such a preparation further generations can be brought up, and in one such case a preparation of the muscle cells of the heart of a chick has been kept alive, growing and dividing, for 12 years—a time far beyond the natural span of the life of the fowl. Such a result proves that mortality is but an accident of the complexity of our living machine, and not a necessary quality and fate of the tissues of which the body is composed. But during these 12 years the muscle cells have not ceased to contract rhythmically, showing that in their peculiar properties must be sought the origin of the rhythmic beat of the heart, thus finally disposing of the various views which have been held, according to which the origin of the heart beat was to be sought in the nervous ganglion cells and fibres present in different parts of this organ.

And it is by the embryological method—i.e., by observing the processes of generation—that Keith and Flack were able to lay the anatomic foundations of our present knowledge of the origin and course of the contractile processes in the heart of the higher animals. In the developing heart, as in the lower vertebrates, the beat originates in that part of the contractile tube which later will form the sinus venosus. In the course of the changes undergone during development, Keith showed that this sinus tissue persisted at definite parts of the mature heart, and could be distinguished under the microscope from the surrounding parts of the heart. This special sinus tissue was given the name of the sino-auricular node and the auriculo-ventricular node.

The brilliant experiments by our distinguished Fellow, Sir Thomas Lewis, have resulted in a complete knowledge of the part played by these nodes in the cycle of the heart's contraction. He has shown how the sino-auricular node is the pace-maker of the heart, how the contractile process originating here spreads through the auricular muscle to the auriculo-ventricular node, and then passes rapidly through the bundle of specialised muscular tissue known as the *a-v* bundle to all parts of both ventricles. We have in this bundle an interesting example of a muscular tissue differentiated to serve the propagation of excitation rather than for contraction, so that it closely resembles nerve in the manner of its function. To the same fine and careful experimenter we owe the explanation of one of the commonest conditions in the diseased heart—namely, auricular fibrillation or delirium, which is responsible for the irregular ventricular contractions, often leading rapidly to exhaustion and failure of the heart. It is remarkable that the clue to the explanation of this condition was first given by the observations of Romanes on the contractile tissue of jelly-fish, which by its rhythmic pulsation propels these graceful animals through the sea-water. It was shown by Mayer for the jelly-fish and by Mines for the frog's heart that it was possible to obtain a ring of contractile tissue in which a wave of contraction passed continuously round the ring, and the merit of Lewis's observations is the proof that delirium is of the same nature as this circus movement, so that the contractile wave continually progresses over the muscular tissue, exciting each part in turn but in a completely incoördinate fashion. It was long ago shown by Marey that the rhythmicity of the heart was bound up with the prolonged refractory period affecting the heart muscle after its contraction, during which period it was insusceptible to any form of excitation. Lewis has shown that the circus movements which are responsible for fibrillation are due to a disturbance in the normal relation between the rate of conduction of the excitatory process and the refractory period in the heart muscle. Thus instead of an orderly procession of impulses from one node to the next and so to the *a-v* bundle and ventricles, every individual fibre is contracting rhythmically but independently of what is happening in its surroundings.

Time will not allow me to deal with the manner in which the heart, already so perfect as it would seem in its power of adaptation, is controlled by the central nervous system, so that the adaptation to changes in the environment and to the needs of the most distant parts of the body can be carried out with greater perfection and with the least possible drain on the energies of the heart muscle. Among such adaptations must be included those attendant on the emotions —" every affection of the mind that is attended by either pain or pleasure is the cause of an agitation whose influence extends to the heart." But, indeed, Harvey's treatise, being the foundation of modern physiology, might serve as a text to a commentary from which but little of our present-day knowledge of the organs of the body could properly be omitted.

I should like, however, to be permitted to allude to another chapter in modern physiology which can be said to have grown out of Harvey's discovery of the circulation of the blood, and which is becoming every day of increasing importance.

The Chemical Integration of the Body.

In the dedication to his work Harvey compares the heart to the sovereign king, and throughout he continually recurs to what we should now describe as the " integrative function " of this organ. In virtue of the circulation which it maintains, all parts of the body are bathed in a common medium from which each cell can pick up whatever it requires for its needs, while giving off in return the products of its activity. In this way each cell works for all others—the lungs supply every part with oxygen and turn out the carbon dioxide which they produce, the alimentary canal digests and absorbs for all, while the kidneys are the common means of excretion of the soluble waste products of the body. Changes in any one organ may therefore affect the nutrition and function of all other organs, which are thus all members one of another. But, in addition to enabling this community of goods, the circulation affords opportunity for a more private intercourse between two or at any rate a limited number of distant organs.

It is now 18 years since I drew the attention of this College to the chemical messengers or hormones which are employed by the body for this purpose. As an illustration of the method by which they work, I adduced the example of carbonic acid, which is the product of all cellular activity, and at the same time has a specific excitatory effect on the respiratory centre, so that the respiratory movements keep pace with the needs of the whole body for oxygen. The typical hormone, however, is a drug-like body of definite chemical composition, which in a few cases is actually known, so that the substance has been synthesised outside the body. It is more or less diffusible, and may even withstand without alteration the temperature of boiling water. It is generally easily oxidisable in a neutral or alkaline medium, so that after its production it does not remain long in the blood ; it delivers its message and is then destroyed. Each specific hormone is manufactured by a group of cells and turned into the blood, in which it travels to all parts of the body, but excites definite reactions in one or a limited number of distant organs. The production and action of these substances are continually going on in the normal animal. They are necessary to health, and their production in excess or in deficit gives rise to disease and maybe to death. Typical of these substances is secretin, a substance produced in the epithelial cells lining the upper part of the small intestine when these come in contact with weak acid, so that it is produced in normal circumstances by the passage of the acid chyme from the stomach into the duodenum. Directly it is produced it is absorbed into the blood and travels round to the pancreas, to the liver, and to the intestinal glands, in all of which it excites secretion. By means of this chemical reflex the arrival of the products of gastric digestion in the small intestine evokes within a couple of minutes the secretion of the three juices whose coöperation is necessary for completing the work of digestion and solution of the food already begun in the stomach. It is probable that this mechanism is but one of a whole chain of chemical reflexes responsible for the orderly progression of the various stages in the digestion of food.

These hormones may apparently be formed by any kind of tissue. In many cases a gland which has, in the evolutionary history of the race, poured its secretion by a duct into the alimentary canal or on to the exterior, loses its duct and becomes a ductless gland, the secretion being now transferred either immediately or through the lymphatics into the blood-stream. In either case these chemical messengers may be formed from masses of cells which have at no time had a glandular structure, and may be modified nervous tissue, germinal tissue, or some part of the mesoblast. As a type of the ductless gland derived from one with an external secretion the most familiar example is the thyroid. The physiological action of its internal secretion and the morbid results of its excess or deficiency, affecting tissue growth and development, metabolism and mentality, are familiar to all. In recent years the active substance has been actually isolated and its constitution determined by Kendal, who has shown that it is an iodine derivative of an amino-acid, tryptophane. It seems almost a fairy tale that such widespread results, affecting every aspect of a man's life, should be conditioned by the presence or absence in the body of infinitesimal quantities of a substance which by its formula does not seem to stand out from the thousands of other substances with which organic chemistry has made us familiar.

But although we do not yet know their constitution, the chemical messengers associated with the reproductive organs are possibly even more marvellous in the influence they exert on the different parts and functions of the body. The effects of castration have been the subject of observation almost from the beginnings of civilisation, but it is only during the last few years that definite proof has been brought forward showing that these effects are due to the removal of chemical messengers normally produced in the testes. The whole differentiation of sex and the formation of secondary sexual characters are determined by the circulation of the blood of chemical substances produced either in the germ-cells themselves or, as seems more probable, in the interstitial cells of the testes and ovary, which themselves are probably derived from the germ-cells of the embryo. Thus it is possible by operating at an early age to transfer male into female and vice versa. Removal of the ovaries from a hen causes the assumption of male plumage; the removal from a young cock of the testes and their replacement by an implantation of ovaries causes a disappearance of the comb and the assumption of the plumage of a hen. Each animal, as concerns its general build and colour, has a neutral form, which, as has been shown by Pézard, results from the extirpation of either testes or ovaries. In fowls the neutral form, as judged by the plumage, approximates the male, whereas in sheep the neutral form resembles the female. There is no question that, by the mplantation of ovaries or testes into the fœtus at a sufficiently early age, one could produce the whole development of the internal and external genitalia corresponding to the sex of the gland implanted. It is worthy of note that these sex characters affect also the mentality and the reactions of the animal, although they are quite independent of any nervous connexions. Here, as in the case of the thyroid, the functions of the central nervous system, in their highest manifestations, depend on the circulation in the blood of chemical substances or hormones. The wonderful development hat takes place in the female after conception to fit her to nourish the fœtus as well as the young child is also due to hormones, produced in some cases perhaps n the ovaries, in other cases in the product of conception itself.

We owe to Schafer the knowledge of the internal secretion of the medulla of the suprarenal bodies. As Cannon has pointed out, this secretion is poured nto the blood during conditions of stress, anger, or ear, and acts as a potent reinforcement to the energies of the body. It increases the tone of the bloodvessels, as well as the power of the heart's contraction, while it mobilises the sugar bound up in the liver, so hat the muscles may be supplied with the most readily available source of energy in the struggle to which these emotional states are the essential precursors or concomitants.

Wonderful, too, is the influence exerted by the ecretions of the pituitary body. This tiny organ, which was formerly imagined to furnish the mucus to he nasal cavities, consists of two lobes which have different internal secretions. That produced by the nterior lobe seems to influence growth, excess producing giantism or acromegaly, while deficiency leads to a retarded growth and infantilism. The posterior lobe, which in aspect would seem but a small ollection of neuroglia, nevertheless forms one or more ubstances which, circulating in the blood, have the most diverse influences on various parts of the body. They cause contraction of the uterus and of the bloodessels (these are possibly two distinct substances), they may increase or diminish the flow of urine, they ffect the excretion of chlorides by the kidney, and, ccording to Krogh, their constant presence in the lood is essential for maintaining the normal tone of he capillaries. In the frog the post-pituitary hormone responsible for the protective adaptation of the olour of the skin to the environment—an adaptaon which is effected by retraction or expansion of the igment-cells or chromatophores of the skin; and, we may accept Kammerer's conclusions, the ituitary hormone which is poured into the blood for his purpose affects the germ-cells themselves, so that dividuals born of parents that have lived in light or ark surroundings are correspondingly light or dark— real transmission of acquired peculiarities effected, ot by the gemmules of Darwin, but by the influence f a soluble diffusible hormone on the germ-plasm.

THE THERAPEUTICS OF HORMONES.

In the multiplicity and diversity of the physiological effects produced by these various chemical messengers one is apt to lose sight of the fact that we are here investigating one of the fundamental means for the integration of the functions of the body. These are not merely interesting facts which form a pretty story, but they are pregnant of possibilities for our control of the processes of the body and therewith for our mastery of disease. Already medical science can boast of notable achievements in this direction. The conversion of a stunted, pot-bellied, slavering cretin into a pretty, attractive child by the administration of thyroid, and the restoration of normal health and personality to a sufferer from Graves's disease by the removal of the excess of thyroid gland, must always impress us as miraculous. In the same way we may cure or control for the time being diabetes insipidus by the injection of the watery extract of the posterior lobe of the pituitary body. The latest achievement in this direction is the preparation, by Banting and Best of Canada, of the active principle normally formed in the islets of the pancreas, and the proof that the diabetic condition in its severest forms can be relieved by its subcutaneous administration.

In my Croonian lectures I suggested that, if a mutual control of the different functions of the body be largely determined by the production of definite chemical substances in the body, the discovery of the nature of these substances would enable us to interpose at any desired phase in these functions, and so to acquire an absolute control over the workings of the human body. I think I may claim that in the 18 years that have since elapsed we have made considerable progress towards the realisation of this power of control which is the goal of medical science. But there still remains much to be done and many difficulties to be unravelled, and it may be worth our while to consider along what lines researches to this end must be directed. There are, no doubt, many hormonic relationships of which at present we are unaware, since every year research adds to their number. But assuming we know that such and such an organ produces an internal secretion which is necessary for the normal carrying on of a given function or functions, we may desire to diminish or enhance its effects in a patient, or to replace it when it seems to be entirely lacking.

There seem to be three possible methods by which we medical men can interpose our art in the hormonic workings of the body:—

(1) In the first place we may find what is the effective stimulus to the production of the hormone, and by supplying this, increase its production by the responsible cells. For instance, we know that by the administration of acid, or at any rate by increasing the passage of weak acid from the stomach to the duodenum, we can enhance the production of secretin, and so of pancreatic juice and the other juices. Probably therefore, when we give dilute acids to assist gastric digestion, we are setting into motion the whole chain of reflex processes in the alimentary canal, and the chief value of our administration may be its effect on the pancreas. But in a large number of cases we do not yet know what is the effective stimulus to the production of these internal secretions. In the adrenals we know the secretion can be augmented through the central nervous system and the splanchnic nerve under the influence of emotions or of lack of oxygen, but we have no knowledge of the factors determining the production of the pituitary hormones or of insulin by the islets of Langerhans, and this condition of ignorance extends to most of the other ductless glands.

In some cases deficient production of a hormone may be due to the absence in the food and drink of some necessary constituent. Thus iodine is essential to the formation of the specific secretion of the thyroid gland (iodothyrin). If iodine be entirely absent from the drinking water and the soil, so that it is not contained even in minute quantities in the vegetable food grown in the district, the thyroid undergoes hyperplasia—in a vain endeavour to make bricks without straw, to produce its proper hormone without iodine. This seems to be the cause of the great prevalence of simple goitre in certain districts, especially in Switzerland and in parts of the United States. It has been shown, by Marine and others, that goitre can be practically eliminated from these districts by the occasional administration of small doses of iodine or iodides. These results were communicated in 1917 to Dr. Klinger, of Zurich, and as a result of his experience the Swiss Goitre Commission has recommended the adoption of this method of goitre prevention as a public health measure throughout the entire State. Already great progress has been made in the abolition of this disease from the country. Thus the incidence of goitre among all the school-children of the canton of St. Gallen has been reduced from 87·6 per cent. in January, 1919, to 13·1 per cent. in January, 1922.

(2) Where a disordered condition is due to diminished production of some specific hormone, we may extract the hormone from the corresponding gland or tissue in animals. It is characteristic of these hormones that, so far as we know, they are identical throughout all the classes of vertebrates, and it is possible that they may be found far back in the invertebrate world. This method is easy when, as in the case of the thyroid, the active principle is stored up in the gland and is unaltered by the processes of digestion, so that we can obtain all the curative effects of the hormone if we administer dried thyroid by the mouth. We have no evidence that any other of the hormones with which we are acquainted partake of this resistance to digestion, so that to produce their specific effects they have to be introduced by subcutaneous injection—a great drawback when the administration has to provide for the constant presence of a small concentration of the hormone in the blood and tissues. In the case of insulin, for instance, it seems necessary to repeat the injection every 12 hours to obtain any continuity of action, and the same thing probably applies to the pituitary extract, while in the case of the genital hormones no reliable effect has been obtained except by the actual implantation of the organ from an animal of the same family.[1] We may, however, look forward to the day when the chemical constitution of all these hormones will be known, and when it may be possible to synthesise them in any desired quantity. We may then be able to overcome the inconvenience of subcutaneous injection by giving relatively colossal doses by the mouth, or we may be able to modify their constitution to a slight extent so as to render them immune to the action of the digestive juices without affecting their specific action on the functions of the body.

(3) The ideal, but not, I venture to assert, the unattainable, method will be to control, by promotion or suppression, the growth of the cells themselves, whose function it is to form these specific hormones. Though this method seems at present far from realisation, the first steps in this direction have already been taken. It must be remembered that the power of controlling growth of cells involves the solution of the problem of cancer. Experiments on the growth of normal cells outside the body have shown that they can be stimulated to vie with cancer-cells in the rate of their growth, or can be inhibited altogether according to the nature of the chemical substances with which they are supplied. And we know that the growth of certain cells, such as those of the mammary gland or of the uterus, is excited by specific chemical substances produced in the ovary or fœtus, and we may be able to find specific substances or conditions for any tissue of the body, which may excite growth when this is retarded or diminish growth when this is in excess. It may be that in some cases purely mechanical interference will suffice. Thus, in experiments by Steinach and others, it has been found that ligature of the vas deferens close to the testis, while causing atrophy of the seminiferous cells, brings about overgrowth of the interstitial cells which, as we have seen, are chiefly responsible for the hormones determining the secondary sexual characters. Among these secondary sexual characters must be classed the whole of a man's energies. Virility does not mean simply the power of propagation, but connotes the whole part played by a man in his work within the community. As a result of this hypertrophy, these authors claim to have produced an actual rejuvenation in man, and thus to have warded off for a time senility with its mental and corporeal manifestations. Further experiments and a longer period of observation are necessary before we can accept these results without reserve, but it must be owned that they are perfectly reasonable, and follow as a logical sequence of many years' observations and experiments in this field.

It would, indeed, be an advantage if we could postpone the slowly increasing incapacity which affects us all after a certain age has been passed. Pleasant as it would be to ourselves, it would be still more valuable to an old community such as ours, where the arrival of men in places of rule and responsibility coincides, as a rule, with the epoch at which their powers are beginning to diminish. The ideal condition would be one in which the senile changes affected all parts of the body suddenly and simultaneously, so that the individual died apparently in the height of his powers. For it must not be thought that in any such way we could prolong life indefinitely. Pearl has pointed out that if all the ordinary causes of premature death were eliminated, this would increase the average duration of life by not more than 13 years. On the other hand, he shows that the children of long-lived parents have an expectation of life which is 20 years greater than that of the average individual. If longevity is our goal it is not medical science we must look to, but eugenics, and I doubt whether the question is one with which we are concerned. The sorrow of the world is not the eternal sleep that comes to everyone at the end of his allotted span of years, when man rests from his labours. It is the pain, mental and physical, associated with sickness and disability, or the cutting off of a man by disease in the prime of life, when he should have had many years of work before him. To us falls the task of alleviating and preventing this sorrow. In our childhood most of us learnt that suffering and death came into the world through sin Now, when, as physicians, we stand on the other side of good and evil, we know that the sin for which man is continuously paying the penalty is not necessarily failure to comply with some one or other of the rough tribal adjustments to the environment which we call morality, but is always and in every case ignorance or disregard of the immutable working of the forces of Nature, which is being continually revealed to us by scientific investigation. In spite of the marvellous increase in knowledge, to some aspects of which I have drawn your attention, suffering is still widespread amongst us. Only by following out the injunction of our great predecessor, to search out and study the secrets of Nature by way of experiment, can we hope to attain to a comprehension o "the wisdom of the body and the understanding o the heart," and thereby to the mastery of diseas and pain, which will enable us to relieve the burden of mankind.

---

[1] In my Croonian lectures in 1905 I reported some experiments made in conjunction with Dr. Lane Claypon, in which I had produced hypertrophy of the mammary glands in virgin rabbits, and in some cases actual secretion of milk by the daily subcutaneous injection of the filtered watery extract of young rabbit fœtuses. Similar results were obtained by Foa. But a weak point in these experiments was that the ovaries had not been previously extirpated. Ancel and Bouin have shown that in the rabbit the mere rupture and discharge of a Graafian follicle, with the subsequent growth of a corpus luteum, are sufficient to cause hypertrophy of the mammary glands (the effective hormone presumably having its seat of manufacture in the luteal cells). It seems possible, therefore, that the effect of our injections may have been on the ovaries, and that the growth of the mammary glands was only a secondary and indirect result. I do not therefore now regard our experiments as conclusive.

THE EARLY TREATMENT OF MENTAL DISORDER.

A CRITICAL SURVEY OF OUT-PATIENT CLINICS.*

By J. G. PORTER PHILLIPS, M.D., F.R.C.P.Lond.,
PHYSICIAN SUPERINTENDENT, BETHLEM ROYAL HOSPITAL, AND PHYSICIAN FOR, AND LECTURER IN, PSYCHOLOGICAL MEDICINE, ST. BARTHOLOMEW'S HOSPITAL, LONDON.

As students of psychiatry we must remember that the human being is merely a biological unit always to be studied and considered by the quality of its reaction to the environmental impositions made upon it by the social body to which it belongs. The late Dr. Charles Mercier, in his "Text-book of Insanity," very ably and clearly explains the relative position of the psychiatrist to his patient. He states:

> "That the student of medicine proper, when commencing his duties as a psychologist, crosses the scientific frontier into a new province, like the shipwright or engineer of a vessel who quits the engine-room to take duty on the quarter-deck. With his acquired knowledge of the structure and working of the craft his function now is to know how the vessel comports herself in wind and weather, and to study charts and tides."

This dictum expressed so aptly in the above simile can be safely taken as the working principle of all psychiatrists, and upon it one can build the whole edifice dealing with the study and practice of early treatment.

Mental disorder in its earliest stage, as most psychologists understand it, is a condition of mind which may more often than not permit an individual to adjust himself to his surroundings and to follow his avocation without ever reaching the stage when the medico-legal label of "insanity" has to be applied to the case. It is very probable that most of us at some time or another suffer in no small degree from an impairment or disturbance of our simple attributes of mind which concern the lower psychological levels, and may thus be victims of mental disorder. In these early phases one is still able to carry out fairly well the essential law of adaptation, and so harmonise with our ever-trying and kaleidoscopic conditions of life. It is well known that the exacting nature of civilised life tends to make itself felt chiefly upon those who are unfortunate enough to be endowed with a weak or unstable mental make-up, and it is to these individuals we have to pay our attention in the form of early treatment. For some generations past we have been teaching the gospel of prophylaxis, and it behoves those who are entrusted with the health of the nation to use every means available to prevent ill-health, whether it be mental or physical. Thus prophylactic medicine, guided by anxious care for health, must forcibly ascertain with greater exactitude the causal connexions within its own field.

Beginnings of Early Treatment.

Much careful thought and valuable work have been exercised in the study and treatment of recognised and well-established mental disease, but it is only of recent years that the early treatment of mental disorder has seriously engaged the attention of psychiatrists. Unfortunately, up to the present moment, those responsible for the framing of the law have made a class distinction as regards the methods of procedure in handling cases of mental disease. For many years past, under the ægis of the Board of Control, opportunities have been offered to private patients desirous of obtaining early indoor treatment in the form of the voluntary boarder system, a scheme which has been in vogue at Bethlem Royal Hospital and elsewhere until the present day, but in the case of the rate-aided or pauper patient no early indoor or voluntary boarder system has existed, and only when the individual had drifted into the zone of certifiable insanity could any actual indoor treatment be offered.

Before the war, at several of the big general hospitals, out-patient clinics were instituted where mental specialists could be consulted, and where work has since been carried out with some measure of success, but in the majority of cases, particularly in those of a psychotic nature, no intensive or prolonged treatment was attempted or thought possible. Indeed, without specially organised departments on the lines pursued in mental hospitals, most general hospitals are not even now in a position to undertake the care and treatment of mental cases. The good which has been accomplished so far by out-patient departments of general hospitals undertaking the treatment of mental cases is beyond dispute, but much remains to be done. Latterly, several specialised clinics have sprung up to deal with this important and difficult problem of early treatment, directing their energies to patients whether of the private or pauper class. In 1919 at Bethlem Royal Hospital an out-patient department was inaugurated, where considerable experience and knowledge has subsequently been obtained by those in charge. Similarly, the Maudsley Hospital, the opening of which has been delayed by war-time exigencies, threw open its doors in 1922 to carry out both the outdoor and indoor treatment of civilians. Furthermore, the Tavistock Clinic, another post-war institution, has been successfully organised and continues to do good work in this direction.

Hospital Accommodation for Early Mental Cases.

The first of the general hospitals to wed psychiatry to medicine proper has been the Middlesex, where three wards have recently been set apart for the reception of early mental cases, the treatment of which will come under the direction of the St. Luke's Mental Hospital staff. In addition, at Brighton the Lady Chichester Hospital has for some years continued to rank as a successful pioneer. It will thus be seen that out-patient clinics for the treatment of mental disease are of comparatively recent growth, but they are already in operation in the United States of America and in Australia. The results to date promise far-reaching effects upon the future treatment of incipient mental disease. The war has strewn the community with nervous and mental wrecks, many of whom are potentially insane, but by no means beyond improvement or ultimate cure, provided a wisely adjusted coöperation between doctor and patient can be secured, with a trained social worker as a connecting link.

"Shell-shock" and Out-patient Clinics.

The problem of the so-called "shell-shock" patient has forced the whole question of the early treatment of neurosis and psychosis to a position of pre-eminence and recurring persistence. If the shock and violence of war experiences resulted in complete inability to face reality, and if by care, understanding, and skilled treatment mental and moral balance could be restored, there is no reason why civilians, harassed and bewildered by their social environment, should not experience a like benefit from similar care and treatment. Neuroses, psycho-neuroses, and psychoses all have a common basic origin in both soldiers and civilians, whether due to shock, nervous instability, continued stress, lack of adaptation, or psychic trauma. In the case of civilian patients, without the glamour of military service in extenuation of their condition, the psychiatric social worker should be of the greatest value in unravelling the contributory causes of mental disorder. In the case of the soldier, the shock or stress may have been only a matter of minutes or hours at the most, whereas in the case of the civilian, the exciting cause of the incompatible social surroundings perhaps have been the burden of years; but the functional damage may be identical in each case. In both kinds of patients one must expect to find a diversity of types, and the most hopeful results are to be looked for in cases where mental and physical collapse was only partial and where the antecedent history was nil. In those cases, especially if the patient was alive to his actual condition and had some insight into the relation of cause and effect, he was successfully encouraged in self-help and to readjust his attitude to the inevitable stress and strain of modern life.

---

* Abridged from a paper read before the Medico-Psychological Association, which will appear in full in the Journal of Mental Science, October, 1923.

For such cases the establishment of the out-patient clinic was the solution of the problem, and if progress has been slow it must be put down to lack of funds. Taxation, trade depression, and the gospel of national economy may retard progress for some time to come, but the seed has been sown, and part of the charitable funds allocated to general hospitals should be diverted for the upkeep of mental out-patient clinics. This action might help to obviate the cleavage and prevent the distinction between the mental and the physical sides of medicine—a state of things far too prevalent to-day.

It might be here pointed out that the difference between the cost of treatment of in-patients and of out-patients is not sufficiently realised by the general public, and, in appeals for funds or statements relating to hospital finance, this difference should be brought to notice. The cost of one patient in a county mental hospital is nearly 30*s.* per week, whereas the cost per patient in a well-equipped up-to-date out-patient clinic would probably not exceed one-tenth of that sum. Even if the cost of maintaining an efficient social service in connexion with the clinics be taken into account, the cost of out-patients' departments is relatively small, when their value as a means of reducing the cost of prolonged care in hospital is shown. By means of the clinics many patients, who would be chargeable upon the State, are kept at home, either self-supporting or cared for by their relatives.

Community Value of Early Treatment.

Early treatment of mental cases is of vital importance to the State if considered from the point of view of community hygiene, and the well-being of the race. It requires little imagination to picture the domestic misery which accompanies mental derangement. The time which elapses between first symptoms and the necessity for certification and removal, or until the patient becomes a direct menace to the family, is filled with anxiety and care for all parties concerned. The patient, himself, fully or dimly conscious of his condition, leads a life of misery, which in itself increases his liability to a final and complete mental dissolution. The immediate members of his family are daily subjected to caprice and outbursts possibly, and the reaction on themselves must, in time, have deplorable results on their nervous systems. The only too prevalent and popular idea of the added stigma of an insane relative holds them back from seeking early professional advice and friendly assistance, and by the time the patient is removed from his environment he leaves behind him one or more members of his family in a state of mental and physical exhaustion, thus adding to the sum-total of avoidable human suffering and economic inefficiency.

Another important plea in favour of the extension of the out-patient clinic system is that it affords opportunities for research which may prove to be of the greatest value in the future social organisation of mankind. The staff of a clinic should be made up of physicians, specialists, nurses, and social workers, all trained upon lines having the same objects in view. Facilities also for routine physical and laboratory examinations, mental tests, X ray, and electrical examinations and therapeutic equipment should be available, from which data can be drawn and a conclusive diagnosis made.

Routine at the Bethlem Royal Hospital Clinic.

In order to elucidate and emphasise any criticism which one may make as the result of practical experience gained in this department, I would like to review briefly the procedure as adopted at Bethlem Royal Hospital for the handling of the out-patients who require early treatment. The clinic is open on Tuesdays, Thursdays, and Fridays. On Tuesday and Friday a psychiatrist and neurologist are in attendance and deal with all cases of neurological and psychiatrical interest, taking full advantage of conference when an exchange of opinion is needed. This system of collaboration between the sister sciences of neurology and psychiatry—a long-cherished idea of mine—fortunately came into being at the inception of our out-patient clinic in Lambeth-road and has proved to be of inestimable value and benefit, both to the physicians and to the patients. In the case of a patient whose condition necessitates further investigation of a specialised character, he is referred to one or more of the specialists indicated by the nature of his symptoms.

Now with regard to those cases requiring some form of psychotherapy. It has been found that under present economic conditions, treatment of this kind is far too costly to be indulged in, other than upon a small scale, owing to its exacting demands made upon the energy and time of the members of the already too small staff. We live in hope that sooner or later larger sums of money will be expended in increasing the working capacity of these prophylactic clinics in the way of added personnel and equipment. Those who do require psychotherapy are carefully selected and attend on an afternoon specially set apart for the treatment of such cases. Patients needing massage or electrical treatment attend the hospital three times weekly, when they are dealt with either by a male or female nurse, as the case demands, who has been specially trained in this branch of treatment. Should any cases suggestive of mental deficiency be encountered which call for further consultation and opinion, the patients are referred to a physician on the staff who attends regularly once weekly and deals specially with them. Pathological and X ray examinations are carried out regularly by the pathologist and radiologist respectively, special attention being paid to the clinical investigation of the blood, urine, and excreta, and for those cases requiring it, intracranial, dental, and visceral radiograms are made. In addition, clinical assistants afford considerable help in compiling notes and supplying other data.

New cases are restricted usually to six at each session, and the procedure in dealing with them is, generally speaking, similar to that which is followed at the out-patient departments of all general hospitals. However, a special warning note may be made here. Under no circumstances is the patient or relative allowed to handle the case-sheet, as is the usual custom in other out-patient departments. This rule is rigidly enforced owing to the fact that I have known impressionable patients and relatives foolishly discussing the medical notes and opinions regarding the case, resulting in injurious effect upon the patient's mental condition. The average number of patients attending each clinic is about 35; the total number of new cases attending during the year was 323; the total number of attendances was 3864. As to average attendances, that for the civilian patient was 4 and that for the Ministry of Pensions case was 12 Each patient is interviewed by the lady almoner, who in this department, acts, in addition, as a social worker—an officer who, as we shall see later, is of the greatest importance. Although it is usually convenient and economical to combine the offices of almoner and psychiatric social worker, it may not always be possible to do so, especially in clinics attached to general hospitals where the almoner's work is already exceedingly heavy. Small charges varying from 6*d.* to 5*s.* for each attendance, are made according to the status of the individual, which is determined by the almoner, and in this way excluding overhead expenses, the clinic, being practically self-supporting, has proved itself, in our case, to be a success from the financial aspect.

Special Difficulties of a Psychiatric Clinic.

The psychiatric out-patient clinic differs in many respects from the out-patient department of a general hospital, more particularly with regard to the data required by the physician for the diagnosis and treatment of his cases. An intimate confidence must be set up between doctor and patient and the personal relationship must be so close that no clinical facts, however trivial they appear to the patient himself, should be overlooked. It is only in this way that the patient will feel that he is really understood and that his case is not hopeless. The physician requires to know the details of his home surroundings, what actions and reactions in the daily round there may be causing strain to himself or his friends. Information of this kind is not easy to elicit from uneducated people, who, in addition to self-consciousness in the presence of those with whom they are not in the habit of associating, have not the mental equipment for a correct and unbiassed relation of facts. They are unable to discriminate between essentials and trifles; they often describe at great length, and not very clearly, what they think they ought to have seen in the patient, but did not. Irrelevancies of this kind waste time and obscure the issue and physicians should not be subjected to this kind of distraction, more especially if the social worker is at hand to prepare the preliminary notes of the case.

The Psychiatric Social Worker.

It is encouraging to know that an experienced worker has also been appointed as almoner and inquiry officer at the Maudsley Hospital, and I understand that a voluntary worker has been trained and attends one or two days a week at the Tavistock Clinic also. It may be here stated that the distinction of being the first out-patient clinic in England to appoint a psychiatric social worker rests with this hospital. It is this officer, who, subsequently, if the case requires it, visits the home of the patient and makes judicious and tactful inquiries regarding the worldly setting of the individual. It is to this officer the physician in charge looks for much valuable information regarding life-history and habits in the case of the patient concerned. It is also to her the physician refers for the details of any social factor which may be present in the environment of the patient which is proving to be a fruitful source of mental irritation to the individual, militating against his well-being. In support of this I may mention that I have oft-times been deeply impressed by the fact that a patient upon whom one would look as a simple case with a favourable prognosis has persistently continued to show signs of mental disorder, and it has fallen to the lot of the social worker to elicit the irritating factor in the social setting of the individual which has proved to be the cause of the breakdown. The importance and value of the assistance she can render the physician can be appreciated only by those who have experienced it.

As a matter of general interest, some may like to hear how the work is organised and carried out by this officer. All new cases coming to the physician are investigated by the worker before their second visit. He then has before him as full a report as possible of the family and personal history of the patient, and a brief account of the salient features in the home environment. After a further examination if any special treatment or change in the surroundings of the patient is recommended, the worker endeavours to make the necessary arrangements. A careful record is kept of attendance, whereby it can be seen at a glance if any patient has failed to attend the clinic for over a month, and a follow-up visit is paid to ascertain the reason. Cases of a purely neurological nature are not investigated in this way, unless for some special purpose and at the request of the neurologist. So much for the individual who requires early treatment of the out-patient order.

The Mental Treatment Bill.

On the other hand, the inmates of a mental hospital, whether voluntary boarders or under certification, present problems several degrees more serious than the really early case. As a general rule, no man or woman enters for in-patient treatment until every means has been tried to control and check the disease, which, if approaching the chronic stage, leaves little for scientific research to accomplish and small hope of amelioration by therapeutic experimentation. The new Mental Treatment Bill is a stride forward in State medicine and should lead to concentration of effort and coördination of methods for dealing with early mental disorder. This Bill gives power to the local authorities, through their mental hospital visiting committees, to provide out-patient clinics for persons suffering from mental disorders (Sec. 1 (2)), allows them to admit voluntary boarders to any of their institutions (Sec. 1 (3)), and gives them power to make provision for the after-care of patients discharged (Sec. 1 (4)).

In another section of the Bill power is given to the local authorities to make grants for research work. But here the public have the course of events in their own hands, for however willing and anxious the local authorities may be to carry out the provisions of the Bill, they will be powerless to accomplish much without the driving force of an enlightened public opinion. The public must be made to realise that the purpose of a clinic is to offer people all the advantages of a mental hospital without the necessity of entering as an in-patient. Moreover, they must be made to understand that the earlier treatment is begun the greater the chance of a permanent cure. Relatives, as well as the patient, would be saved much misery and ill-health by making use of the clinics at the first sign of nervous or mental instability. To ensure this there should be greater collaboration and more ready conference between the general practitioner, who may see the case in its initial stages, and the psychiatrist, who presides at the clinic.

The Mental Treatment Bill is of vital importance to the community and is a reform which should have behind it a genuine public interest, so that local authorities may spend the Government grants wisely and well; otherwise, progress will be slow, difficult, and costly. It should not be difficult for medical and social workers to reach the unstable elements in our midst, and to make adjustments by which they can often be prevented from needing the protection of an institution.

Education of the Public.

The secret of modern progress often lies in propaganda. In the United States of America and in Canada much has been done to educate the public and to enlighten them as to the best means of facing the problems of early mental disorders. In this country intensive propaganda is never likely to be carried to the extent which obtains in the States, where it has been brought to a fine art. We have recently had an example in which a persistent minority has forced and carried its views over the heads of an unwilling majority, the result being a remedy worse than the disease. But there is no reason why an organised propaganda in this country should not attempt to arouse the public conscience to its obvious duty in the matter of early mental disorder in the adult and defective mentality in the child. It should be the duty of every psychiatrist to educate the minds, not only of patients and their relatives, but also those of our medical brethren, to accept the fact that mental disorder is a common everyday illness, with which no stigma or sinister atmosphere should be associated.

Other countries, however, do not rely on propaganda alone. Attached to all mental out-patient clinics will be found the highly-trained psychiatric social worker. This again is a sphere of activity strongly developed in the States, where qualified laymen and medical practitioners work side by side, the work of one being complementary to the other. For example, some State medical officers of health are not medical practitioners, but they must be doctors of hygiene or diplomates in public health. These qualifications are granted after a course of study and examinations, the possession of a medical degree not being an essential condition of entry. The social workers receive an equally intensive training. They are trained in colleges adapted for the purpose, and are selected because of their understanding of human psychology and physiology. They are expected to deal with the patient in his social setting as intelligently as the psychiatrist deals with him in the clinic.

Education of the Social Worker.

The selection and training of social workers is of the utmost importance, having regard to the intimate association they must cultivate with the patients if they are to appear to them as guide, philosopher, and friend. A social worker must not only possess a sympathetic nature, but must have that understanding of mental patients born of experience in dealing with them. Her grade in society must have brought her into contact with all sorts and conditions of people, and especially with persons connected with or interested in homes and institutions, and also with others charitably minded. It has to be remembered that she enters homes overshadowed with disaster, and without the entire confidence of the inmates she is not likely to probe beneath the surface of a subconscious and protective reserve. She must first of all win the coöperation of the patient, without which he will never feel himself really understood. The way will then be paved for obtaining a full history of his condition and the causes leading up to his mental state. For the first time, perhaps, he will feel the stimulus of hope, and her presence will be a moral support when he and his family realise that she is part of the scheme of things intended for his treatment and cure. His home surroundings and the social environment in which the family moves must be ascertained by direct questions, and where satisfactory answers are not forthcoming, a well-trained worker will be able by veiled but acute observations to discover any constant or deep-seated factor militating against the patient's well-being. Only thus will it be possible to readjust him to his normal surroundings.

It might be considered advisable to standardise inquiries up to a certain point, leaving the social worker to use her own discretion as to supplementary questions. As an indispensable link between the physician and the social world in which the patient has to live, she will be able by repeated visits to complete the clinical picture, especially the antecedent history. This applies more particularly to civilian patients without a definite cause for the onset of illness. Without attempting anything in the nature of a medical examination, she may in some cases be able to fix the cause of an anxiety neurosis of one sort or another. There may be domestic reasons for a fixed idea which the removal of a patient would end or mend. By repeated visits she would be able to ascertain his mental outlook, and with simple suggestion divest his symptoms of their terror. Apprehension would cease to trouble him and his economic efficiency would be increased; likelihood of relapses would be lessened.

The social worker by expanding her sphere of activity would render specially valuable help in the case of feeble-minded children and the young delinquent. By access to school teachers she would gain particulars as to a child's habits and reasons for backwardness at school. Mental twists and peculiarities of conduct would be noted, and how far re-education and a different environment might be likely to benefit the case upon the advice of the physician who has charge of it. By associating herself with special cases appearing before the police courts, and conferring with the missionary and probation officers, much profitable work could be carried out and useful data collected. One of the items on the programme of the National Council of Mental Hygiéne is the promotion of social service in connexion with out-patient clinics, and it is to be hoped that in time at least one such worker will be attached to every out-patient clinic for nervous disorders.

Conclusion.

In reviewing the vast, complex, and far-reaching problem of early treatment, it must at once be acknowledged that the medical or scientific side, although falling short in a large measure in the past, is now attempting to supply its full quota of help. However, this is not a solution to the difficulties; it merely serves as a half-way measure, and we must now penetrate as explorers still further into the jungle of life, in order to succour or even extricate the weary or fallen wayfarers, who, from a lack of mental and physical equipment, have been unable to journey through the tangled undergrowth of disharmonies. Fundamentally, the problem as detailed above proves itself to be one not only beset with obstacles, but also presenting a promising outlook, and, in order to ensure success, must of necessity resolve itself into a question of mental hygiene backed up by the vigorous support of eugenics and euthenics. It would now appear that we have reached a stage of civilisation when social organisation is increasingly urgent, especially when one faces the fact that social evolution is taking place at an extremely rapid rate.

All those who are interested in the question of early treatment must welcome with open arms the inauguration of the National Council of Mental Hygiene. This body has wisely elected to its executive men and women who from their training and experience are well qualified to undertake the intricate and onerous task of social readjustment in so far as it concerns the mentally unstable. To their activities we shall look with great interest and with the fervent anticipation that a really practical and coördinated scheme will be formulated to improve and facilitate the working principles which at present exist. We thus hope that by their help out-patient clinics will be linked up in closer association with the executives of the general hospitals, mentally defective organisations, and after-care associations.

A NOTE ON

ACUTE *BACILLUS COLI* INFECTION OF THE GASTRO-INTESTINAL TRACT

IN THE NEW-BORN CHILD CONTRACTED FROM ITS MOTHER.

By R. CHALMERS, M.D. Aberd., F.R.C.S. Edin.,
ASSISTANT SURGEON, GREENBANK HOSPITAL, DARLINGTON.

In the issue of The Lancet dated July 21st, 1923 (p. 118), Drs. R. C. Jewesbury and L. S. Dudgeon reported a most instructive case of this infection with the fullest details. In view of the correspondence that has taken place with regard to Lady Barrett's article on "The Prophylactic Treatment of Puerperal Sepsis"[1] in which she emphasises the need for clearing up all foci of infection in the mother before confinement—I should like to point out to all who have disagreed with her article, first, how this case confirms Lady Barrett's contention, and, secondly, that this is one of a series of articles on "*Modern* Technique in Treatment."

My attention was drawn to the above articles by a conversation I had—while waiting on a confinement—with the matron of a nursing home who keeps herself abreast of the times by taking The Lancet I had expressed the opinion—from recent observation of several cases—that I believed a great deal of the gastro-intestinal disturbances of early infancy was the result of a toxæmia in the mother, acting on the fœtus in utero. Early jaundice, flatulence, vomiting, and difficulty in finding a suitable diet were always more in evidence in children of mothers who were in a toxic state while carrying. Whether the infection is ante-natal, during birth, or post-natal it is often difficult to say, all three seem to be possibilities. The combination of a streptococcal infection with a *Bacillus coli* is another point I have been coming to; for I believe there is often a double infection in the mother in these cases—the streptococcal infection being primary and the *Bacillus coli* infection secondary.

---

[1] The Lancet, 1923, i., 1279.

The following cases have a bearing on the discussion.

CASE 1.—Married woman. Admitted to hospital about fourteenth day after confinement with history of rigors. Temperature and swelling of legs (phlebitis) occurring three or four days previously. Uterus douched but nothing abnormal found. Temperature 101° F.; hæmoglobin 70 per cent. Tongue dry; marked insomnia, headache, and anorexia. *Bacillus coli* in urine; unclassified diplococcus (? strepto-diplococcus) found in blood. Treatment with potass. citras. and catalysers; distinct improvement in a few days; natural sleep, headache gone, ravenous appetite, feeling of well-being, *but* an acute gingivitis with pus developed at the gum margins.

CASE 2.—Married. Suffered from liverishness. Later had appendix removed. Still not feeling well. Two attacks of basal pneumonia with pleurisy within a year. Later became pregnant. Child jaundiced on second day after birth. Very flatulent, sick, vomiting of mucus and food; ill for several weeks. Always troubled with an atonic condition of rectum. Later mother showed pyorrhœal condition for which a total extraction was done. This was followed in three days by a recurrence of pneumonia and pleurisy. A vaccine made from the sputum, which contained large numbers of streptococci, pneumococci, and *Micrococcus catarrhalis*, cleared up the condition. No note as to *B. coli* in urine.

CASE 3.—Married woman. Suffered from severe fibrositis and sciatica. Later had her appendix removed. Then on becoming pregnant developed a most intractable urticarial condition. Child most difficult to rear. All kinds of digestive disturbances. This patient has a recurrence of her skin irritation on becoming pregnant again. Marked streptococcal apical infection of the teeth all the time. No note as to *B. coli* infection.

CASE 4.—Married woman. Suffered from very intractable constipation. On becoming pregnant showed a marked *B. coli* infection of the urine. About ten days before confinement had an acute exacerbation of the urinary condition with temperature, constitutional symptoms, marked insomnia, backache, &c. Child became extremely jaundiced with marked flatulence and digestive disturbance on the second day after birth. Streptococcal foci present in the teeth.

CASE 5.—Married woman, aged 50. Sallow complexion, with dark rings below eyes. Typical poisoned facies.

Previous History.—Suffered from what was called a rheumatic rash on knees and elbows (erythema papulatum) seven years before. Some years later suffered from a rash on hands which was called erythema multiformæ and was diagnosed as due to contact with ivy. In autumn of same year (now two years ago) she suffered from herpes of nerves supplying the external genitals. Still later began to notice a blood-stained uterine discharge.

Condition on Examination.—A discharge was seen coming from the cervix with slight congestion of the os uteri, but no erosion. A large tumour could be felt posterior to the uterus.

Operation.—The tumour on removal proved to be a large parovarian cyst; the uterus and tubes appeared normal.

Course of Case.—About the tenth day after operation she developed a rise of temperature with swelling (phlebitis) in left leg. This had been preceded by marked gastro-intestinal disturbance, flatulence, anorexia, and great depression. Urine revealed oxalates, indican, but no *B. coli*. The uterine discharge returned. After about six weeks of rest and douching and not much improvement in leg or uterine condition, a search for a focus of infection was made. Although the three teeth she had remaining had been examined previously and passed as healthy, on re-examination small pockets were found in the gingival margin. Extraction of the teeth revealed marked streptococcal infection of the periodontal membrane.

Bacteriological Report.—The bacteriological examination of a swab from the cervix showed heavy infection with *B. coli* and streptococci; fæces showed *B. coli* of Friedländer type and excess of streptococci (unclassified).

CASE 6.—Age 45. Had a uterine polypus removed. Suffered from constipation and *B. coli* infection of urine with associated debility and anæmia. Later, after vigorous manual exercise, suddenly developed a painful swelling in breast (lobular mastitis). This settled down with rest and autogenous vaccine for the *B. coli* infection. None of her own teeth. Previous condition of mouth not noted.

CASE 7.—Aged 40. Had suffered from neuritis and rheumatoid arthritis for past three years. Frequent liverish attacks with flatulence. Had her appendix removed. Later *B. coli* infection of urine, then colitis, followed by interstitial mastitis for which the breast was removed. Still later an acute inflammation of fauces and tonsils with recurring epistaxis. No virulent organisms present on report from swab taken. On re-examination of teeth (X ray and bacteriological) showed marginal pyorrhœa and marked streptococcal apical infection.

Summary.

Case 1 shows the connexion between *B. coli* and most likely streptococcal infection, the latter probably arising from the gums.

Case 2 shows the streptococcal infection of the mother with marked toxic effects on the child. Note the rectal atonic condition of the latter—a symptom I believe to be due to the streptococcus poison. Parenthetically it also shows the risk of complete dental extraction in a patient with marked toxæmia. Important are Sir William Willcox's warning on this point—viz., that the presence of a leucopenia is a danger sign—and Sir Almroth Wright's explanation of the possibility of the leucocytes being poisoned to such an extent as to lose their phagocytic power.

Case 3 shows the effects of toxæmia in the mother—arising from a streptococcal infection—where the extra strain of child-bearing upsets the defensive powers of the body. Also, the prolonged digestive disturbances in the child are probably the result of the ante-natal toxæmia.

Case 4 shows the relation of *B. coli* injection in the mother with marked jaundice and prolonged gastro-intestinal symptoms in the child.

Case 5 shows evidence of a toxæmia going on for a period of years, as evidenced by the skin rashes, followed by a herpes zoster, which is said to be due to a streptococcal infection of the posterior root ganglia. The fact that it is the nerves of the external genitals that are involved in the herpetic eruption and that the genital organs later show morbidity is probably more than a coincidence.

That the uterine discharge contains streptococci and *B. coli* shows the possibility of the child becoming infected with mucus in its sojourn in the maternal passages. The focus of streptococcal origin seems to be the teeth, and it appears that the uterine mucosa often acts as an excretory organ for these organisms or their toxins. It may seem very unorthodox, but I am inclined to think that many of these uncontrollable menorrhagias with redundant mushy endometrium, and fibrosis uteri, and even carcinomatous changes, are often due to some toxic factor arising in this way in the system. Witness the association of mastitis (fibrosis) in Cases 6 and 7. One with streptococcal infection; the other with *B. coli* and uterine polypi.

Relation of Reported Cases to B. coli *Infection in Infants.*

Streptococci and *B. coli* have been present in several of the cases reported. So also in the mother of the case reported by Dr. Dewsbury. She evidently was in a very toxic state—her heart probably bearing part of the brunt of the poison. She was excreting streptococci by the breasts and in urine and lochia, and *B. coli* by urine and lochia. One wonders whether she had not some focus for her streptococcal infection in mouth or throat. If the biological history of a large number of intestinal diseases is investigated, it will very frequently be found that a clue to many of these cases is the presence of streptococcal infection in mouth, naso-pharynx, or sinuses. I believe that a great number of these *B. coli* infections are stirred up, or their exit from the intestinal tract made easier—by the injury inflicted upon the intestinal mucosa by the streptococcus or its poison. I believe, too, that the neuro-muscular paresis with resulting stasis is caused by the streptococcal poison and consequent putrefaction. Just as in some intractable staphylococcus infections no improvement is obtained until a co-existing streptococcal focus is cleared up, so also with *B. coli* infection; I believe there to be a symbiosis between them. Perhaps this is one of the reasons why Mr. D. P. Wilkie finds such benefit from prophylactic infections of the combined vaccine prior to operations on the lower intestinal tract.

Although the condition of the mother amounted to a bacteriæmia, no organisms were reported from the blood examination. Kidd, however, has shown that the *B. coli* germs can be found in the blood-stream if the blood is examined about the time of the rigor. There is no mention of the child being jaundiced as one would expect if the infection was from swallowing of infected mucus. It seems to have developed on the third day, after several feeds of breast-milk which was heavily infected with streptococci.

The two cases of mastitis (Cases 6 and 7) show the affinity of the streptococcus and *B. coli* germs (or their toxins) for breast tissue; also the affinity of these organisms for the physiologically associated organ, the uterus—as in Case 5.

Darlington.

THE TREATMENT OF SPRUE

BASED ON A NEW THEORY OF CAUSATION.

By H. HAROLD SCOTT, M.D., M.R.C.P. Lond.,
D.P.H., D.T.M. & H. Camb., F.R.S. Edin.

(From the London School of Tropical Medicine.)

Early in 1923 my preliminary communication on a New Theory as to the Causation of Sprue was published in the Transactions of the Royal Society of Tropical Medicine and Hygiene. By the kindness of the physicians to the Hospital for Tropical Diseases, Endsleigh-gardens, I have within the last few months been given opportunity for putting the treatment based on that theory to the test in several cases with such marked success that I think the time has come to place a few of them on record and to speak in a little more detail of the theory and its application.

Sprue is a disease which appears to be considerably on the increase in recent years, especially in the East; it leads to much sickness and incapacity, is the cause of extensive invaliding from the tropics, and is responsible for not a few deaths. Treatment of the disease is almost entirely empirical and the results very uncertain, return to the tropics being, in a large majority of cases, followed by relapse usually within a short space of time.

Case 1.—Male, aged 48, born in England; in South Africa 1902–05, in the West Indies (Jamaica) 1910–19, in China 1919–21. With the exception of an attack of enteric fever in 1918 he enjoyed excellent health until the onset of symptoms of sprue in 1920. During the next 18 months practically every known form of treatment was tried—milk, the Salisbury diet, liver soup, emetine injections, vaccines, yellow santonin, with only temporary benefit, any attempt to pass on to ordinary diet causing a relapse. This case was severe, all the typical symptoms being present—acidity, flatulence, marked mouth symptoms, large, pale, frothy, pultaceous motions, troublesome cramps in the limbs, loss of over 3 stone in weight. At one time, apart from general tenderness of the tongue, there were over 30 aphthous patches on the tongue, frænum, and buccal mucous membrane, and, judging from the pain on swallowing, probably along the œsophagus also.

New Treatment.—The patient was invalided to England, arriving March 22nd, 1922, and was taken into hospital the following day. Improvement followed a strict milk diet, but within six weeks of leaving hospital a relapse occurred in July, another in September, and a third in December, by which time the condition was almost as bad as it had ever been. There was troublesome acidity, with aphthæ in the mouth, a tender, raw, red tongue, and cramps. The weight had decreased by nearly 2 stone; the stools, which had become a little darker in the intervals between the relapses, though never normal, were again pale, large, and frothy. Calcium lactate, 10 gr. in cachets, was given twice daily, the dose being increased to 15 gr. a few days later, and then thrice daily. Some improvement followed, but in another fortnight, in spite of the continuance of the calcium, matters returned to their former state. Blood tests showed that the total calcium content was not diminished and the inference was that, if the calcium was at fault, the error lay somewhere in its regulation and metabolism. On Jan. 8th, 1923, the calcium lactate was reduced to 10 gr. three times a day, and a small dose, 1/20 gr. parathyroid extract (Parke, Davis and Co.), morning and evening. The symptoms were checked, but there was no definite improvement, so on the 16th the latter dose was increased to 1/10 gr. twice daily. There were then four very painful aphthæ in the mouth and a small tender papule. The latter usually preceded the ulcer stage by 48 hours or so. By Jan. 22nd the papule had not developed, but had disappeared, three of the ulcers had completely healed, and the other, the largest, was nearly well and was no longer painful, and the tongue was very slightly tender. Two days later the stools were formed, brownish in colour, and rarely more than one a day. There was a feeling of well-being, and there had been no cramps since the 20th. On Jan. 30th the parathyroid was reduced to half the dose, and the diet, which had been restricted to milk till the 24th and milk puddings subsequently, was increased to include fish, chicken, and vegetables. By Feb. 10th ordinary full diet was being taken, and on the 12th both drugs were discontinued. There had been no fresh aphthæ or cramps, and the stools were formed and almost normal in colour. The weight rapidly increased, and by March 10th had reached 2 lb. above the normal for the previous 15 years. Since then the patient has been on ordinary diet, doing full work, and there has been no set-back whatever, nor sign of any relapse.

This case has been recorded fully because it was the first in which the new treatment was tried. The remainder may be described more briefly.

Case 2.—Female, aged 40, married, two children. Born in Ceylon, came to England at the age of 12 years, returning to Ceylon in 1912 and staying there for three years, during which period she had an attack of dysentery and of dengue. In 1919 she went again to Ceylon, and had good health until May, 1921, when she suffered for a week with a sore and tender tongue. For the succeeding two months she was free from this, but thereafter had frequent recurrences, together with indigestion, heartburn, and flatulence, with large, pale, frothy stools.

New Treatment.—This state of affairs continued until September, 1922, when the patient was sent to England. A week later her condition was recorded as follows. Tongue sore, tender and red, with ulcers on frænum, cheeks, and gums, motions large, pale, frothy, especially in the early morning, but not infrequently during the day also. She was treated at home by restriction to milk diet, but though the number of motions was reduced they remained very pale, and the weight steadily diminished. She came into hospital on Feb. 15th, her weight then being 107½ lb. She was given calcium lactate, 10 gr. t.i.d., with parathyroid, 1/10 gr., morning and evening, together with a plain milk diet; in a week the aphthæ had cleared up and no fresh ones had appeared. The stools on admission were typical. At the end of the month—i.e., a fortnight after starting the treatment—the colour was coming back in the stools, though they were still pale. She was then given Benger's food in addition, and the heartburn and flatulence returned, but ceased when the food was taken off. The weight improved and by March 11th was 111¼ lb., and she was taking biscuits, fish, milk puddings, and eggs. She left hospital a fortnight later. All medicine was stopped during the first week of April. The weight continued to increase till it reached her normal (9 stone), and there has been no return of symptoms.

Case 3.—Male aged 62. Born in Scotland; went to the tropics (San Domingo) in 1888. In 1896 suffered from "ulceration of the mouth," which cleared up with local treatment. He had yellow fever in 1896; and returned home in 1898. Was in the West Indies again in 1905, 1910, 1912, and 1921. In 1909 he suffered from recurrent attacks of diarrhœa, with a tender and painful tongue and loss of weight. These symptoms recurred intermittently for the next 11 years. By 1921 the diarrhœa was persistent; the condition was diagnosed "intestinal catarrh," but did not yield to treatment. The following year a specialist diagnosed "chronic pancreatitis," but no treatment proved of any avail. In 1923 a third physician told him that the disease was sprue, and he was put to bed on strict milk diet. He remained there for four months; the diarrhœa was checked in some degree, but returned whenever an increase in diet was attempted. For two months he lived on milk and strawberries and thinks he benefited at first, but a relapse came on while this diet was being continued.

New Treatment.—On May 11th he came to the Hospital for Tropical Diseases, and, by the kindness of Dr. P. Manson Bahr, I saw him. He started the calcium lactate an parathyroid treatment on May 13th. The symptoms were typical—a sore and tender mouth and tongue, acidity, flatulence, large, pale, pultaceous stools. Within a week the diarrhœa ceased, the motions were formed, and the colour brownish. In a fortnight he was taking eggs, toast, Mellin's biscuits, milk puddings, baked apples, and bananas. Progress was uninterrupted, and he left hospital in June, having put on over a stone in weight. He went to stay at a hotel in Tunbridge Wells, and in September wrote to me saying that, as directed, he had gradually reduced the medicine and stopped taking it four weeks after leaving hospital, and had not had to return to it. "My diet," he writes, "has been just the same as that of everybody else in the hotel. . . . It seems to suit me quite well. . . . My weight has increased by another 4 lb., and I feel well." After five weeks in hospital he has apparently recovered from a disease which has troubled him for over 14 years.

CASE 4.—Male aged 21. Contracted sprue in India; in July, 1922, at Bombay, he suffered from diarrhœa with large, pale, porridge-like stools, indigestion, acidity and flatulence, and a raw tongue. This continued; he went to Simla in March, 1923, having then four or five of these motions daily. Emetine injections were given without producing any benefit.

New Treatment.—He was invalided to England, arriving June 7th. On admission to a nursing home he showed: Tongue raw, red and tender, fungiform papillæ prominent, abdomen distended, especially the lower part; he was passing very large stools (26–30 oz.), pale, frothy, and loose. Weight on June 19th 111 lb. He started calcium and parathyroid treatment on June 12th. By the 21st the soreness of the tongue had disappeared, and there were no dyspeptic symptoms after the 24th; by the 26th the stools were light brown in colour, only one a day, and the weight of them varied between 6 and 13 oz. He expressed himself as feeling very much better generally. At the end of the month he was well enough to go out for walks daily. His weight in successive weeks from June 26th to July 23rd, when he left the nursing home, was 112, 113, 118, 122½, and 128 lb. He ceased taking the medicine a fortnight later, and reported two months afterwards; he then looked and said that he felt thoroughly well; he was taking full diet, his weight was 154 lb., and he is about to return to India.

I have notes of six other cases, but to record them in detail would be practically a repetition of the above. The following case, however, ought not to be omitted as a set-off against the almost uniform success obtained in cases treated up to the present. This patient was in extremis when first seen, and the treatment was tried solely to satisfy the heart-rending request of the patient's husband that "something might be done as she seemed to be dying." Even here an unexpected temporary improvement followed:—

CASE 5.—Female aged about 50. Had suffered from sprue for many years; was in hospital on that account five years ago and improved, but relapsed very soon afterwards and had never been well since. Normal weight about 126 lb. When seen on April 14th she said she felt very weak, and her weight was only 79 lb.; her mouth was very sore, there were several aphthæ, and she was taking hardly any nourishment at all because of pain and weakness. She was intensely anæmic and very short of breath. She was passing five to six motions daily, pale, bulky, pultaceous, and frothy.

New Treatment.—She was at once put on the calcium and parathyroid, and a week later expressed herself as feeling "better in herself" than she had done for many months; stools three daily, less bulky, some formed, becoming darker in colour, not frothy; the flatulence was much less troublesome, and the ulcers in the mouth had cleared. In another week the stools were reduced to two or three daily and were more formed. Although she said she felt better and would like to get up, she was too weak and was obviously losing strength. Her weight on April 28th was only 73 lb. She became progressively weaker and unable to take nourishment, and died a few days later.

Remarks.

The average stay in hospital of the cases recorded above has been five to six weeks, and none so far have relapsed. The intervals since cessation of treatment vary between two and eight months. This is in marked contrast with the usual histories of as many months in hospital as weeks in the above cases, succeeded by a prolonged period of restricted diet and a constant tendency to return of symptoms, if not, as in many cases, an actual relapse.

The theory, as stated in my preliminary communication referred to above, is this: In the endemic areas of the disease conditions are such that there is an excessive proteid diet (in India, Ceylon, and other parts of the East), or a diet containing an excess of fat largely contributed to by the method of cooking the food (in China and the West Indies). Excess of proteids stimulates over-production of acid in the gastric juice and may lead to habitual over-acidity. The entrance of acid into the duodenum stimulates the production of secretin, which in turn leads to over-stimulation of the pancreas, and, secondly, to an upset in the balance of other endocrine glands, among them the parathyroids and salivary glands. Evidence is accumulating that endocrine disturbance and alimentary toxæmia are frequently associated, and all acute and chronic toxæmias react in some degree on the parathyroids, causing disturbance of calcium metabolism and a consequent decrease in tissue resistance, a vicious circle being thus set up. It will be of interest to speak of a few of the chief questions here raised in a little more detail.

1. *Evidence of Over-stimulation of the Pancreas.*—In the fæces the ratio of neutral fats to fatty acids is normally as 1 is to 2. In cases of pancreatic disease and insufficiency this relation is more than reversed and may be as high as 15 to 1. In conditions of increase of pancreatic action one would expect a greater splitting up of neutral fats and the proportion of these to fatty acids would be less. Now, in a mild case of sprue, the proportion is found to be as 1 : 3 or 1 : 4; in a moderately severe case as 1 : 4 or 1 : 5, and in graver cases even up to 1 : 9. Confirmation is also obtained clinically. In several instances, as improvement took place, the nutriment was increased by the addition of pancreatised food with the idea that this would help digestion and enable the patients to put on weight. Within a very short time—in some at least, especially in those with hyperchlorhydria—symptoms reappeared, and such patients have again and again stated that they wished to go back to milk as they felt worse after each meal of this food. Again, the work of others has shown that the internal secretion of the pancreas reacts on other endocrine glands and on the salivary glands. I suggest that the sore and aphthous condition of the tongue and mouth may in part be due to altered salivary secretion, for the reaction of this in severe cases is acid to litmus. The glossitis and stomatitis are also ascribable to alimentary toxæmia (see below). In Case 1 it was a notable feature that a bout of excessive acidity preceded an aggravation of the mouth condition, and a fresh crop of sore spots would appear within 48 hours.

2. *Evidence of Errors in Calcium Metabolism.*—This term is preferable to "calcium deficiency," because in the majority of cases in which blood-calcium estimations were carried out the *total* calcium content was approximately normal. Decrease of calcium, as the researches of Vines have shown, may be of two types: It may be absolute when the total amount in the serum is lessened, or it may be relative when the total is unchanged but some of the calcium is bound, so that the complex formed is not assimilable by the tissues. In either case the effect on the somatic cells is the same; they suffer from a deficiency of calcium which they can utilise. The "ionic" calcium of the blood becomes deficient in cases where chronic toxæmia is present, and this is what, in my belief, occurs in sprue. The striking factor common to the tetany, cramps, œdema (in severe cases), the loss of weight, excess of excretion of calcium salts in the fæces, the ulcerative condition of the alimentary tract is their relation to deficiency or faulty metabolism of calcium. As stated, the total calcium proved normal or nearly so in the cases tested, and the coagulation time is not extended, so that the probability is (further tests are to be carried out to confirm this) that there is a change in the normal relations of the "ionic" calcium to the "coagulative" or "combined." When calcium is administered in sprue the increase makes up temporarily for the deficiency and the symptoms improve, but it was found repeatedly that

this improvement was transient, and the dose had to be increased. The total calcium of the blood being about normal, one naturally inferred that it was the regulation of the calcium which was disordered; accordingly, the dose prescribed was reduced, but parathyroid extract was given at the same time, with the results detailed. The parathyroids have two functions, (1) detoxication, and (2) control of calcium metabolism: but these cannot be rigidly separated. The action of parathyroid substance is physiological and is not apparently specific against any one organism or toxin. "Its action is to place the tissues of the patient under conditions more suitable for the performance of their normal functions and for combating the effects of toxic processes"; also "when there are lesions due to such (toxic) states healing does not commence until the ionic calcium of the blood approximates the normal figure" (Vines). Hence, the rationale of the treatment above—bed, on a diet of milk (partly because of the ulceration, partly because of the calcium content), and the administration of calcium and parathyroid until the mouth ulcers are healed, when one may infer that the intestinal ulcers are on the mend also, and an increase in diet is then allowed. It is essential that the parathyroid should be guaranteed. The antagonism between thyroid and parathyroid is well exemplified in this disease. If an impure product is used the symptoms return almost at once.

3. *Evidence of Alimentary Toxæmia.*—This condition is practically self-evident. The acidity, the flatulence, the secondary anæmia, sometimes of severe degree, and the ulcerative state are all indicative of this. Further, the bacterial examination of the fæces reveals unusual organisms, monilia in one case, special forms of streptococci in another, aberrant coliform bacilli in a third. Such toxæmic conditions react, as Vines has shown, on the parathyroids. Possibly the special organism isolated constituted, as it were, the last straw which broke down the function of the over-worked parathyroid, and hence the benefit reported by some from the injection of autogenous vaccines in sprue cases (see below).

A few words may be written relative to the modes of treatment chiefly in vogue at present.

(*a*) *Milk.*—This, as already stated, constitutes a non-irritating food, allows the ulcers to heal, and is a good method of administering calcium. During the first fortnight or so it is practically the only food under the form of treatment indicated in the present paper, and nothing further need be said.

(*b*) *Salisbury Treatment.*—This diet, consisting of scraped meat and hot water, would probably act best in cases associated with hypochlorhydria, as by a radical alteration of diet it may bring about a change in the intestinal flora and so remove the source of the toxæmia. The régime is persisted in for six weeks or so, and then an increase of diet is very cautiously permitted with warnings to return to it at the first sign of recurrence of symptoms. Cure is rarely prolonged.

(*c*) *Emetine Injections.*—Emetine was probably given primarily because many cases give a history of previous dysentery. Its action as regards sprue in those cases which have come within my cognisance has been nil.

(*d*) *Liver Soup.*—This is perhaps given on the erroneous idea that, because the stools are pale, bile is absent and the liver is not acting; the prescription is analogous to that of ovarian extract for sterility, and similar barbaric empiricisms. Some writers, it is true, report good results, but we must bear in mind the fact that it is usually given with milk and other nutriment, while no reason has been given for ascribing any specific beneficial effects to the soup.

(*e*) *Vaccines.*—These, as has been pointed out, probably prove beneficial (in the rare instances in which they do so) by putting out of action the chief organism responsible for the toxæmia and so relieving the overworked detoxicating function of the parathyroid. This gland is again enabled to cope with its work, but the effect of vaccines is uncertain and relapses are common. Thus may be explained the fact that the vaccines employed and found beneficial are so varied, one finding a streptococcus of some sort, another a monilia, a third some form of *Bacillus coli*. Those of the above-recorded cases who had had vaccines derived no benefit at all; moreover, these organisms are probably only subsidiary, because nearly all the above cleared up without the use of any vaccine, with great rapidity, as the histories show, and so far there have been no relapses.

(*f*) *Strawberry Cure, and* (*g*) *Santonin.*—These are given empirically. I know of no rational explanation of their actions. They are never employed alone, so it is difficult to say, in fact it is merely a matter of conjecture, as to what degree the amelioration, if it occurs, is ascribable to the fruit or the drug.

Finally, though the clinical results have been so fortunate, there are several questions as to the pathogeny of the disease still calling for elucidation. Such, for example, as:—

1. Why does not the disease occur in Europe? Possibly it does.[1] Pellagra was for a long time overlooked in this country. All of the cases of undoubted sprue which I, personally, have seen have resided abroad, though some had returned from the tropics several years prior to the onset of symptoms. But the condition spoken of as cœliac diarrhœa bears a strong resemblance to sprue—the loss of weight, the bulky, pale, frothy stools, the flatulence, and dyspepsia. One patient who had suffered for months in this way was put upon the same line of treatment as that indicated above and told to report again later. She, however, sent word to say that the symptoms had cleared up in less than a fortnight, and that she felt well, but would come again should the symptoms recur. Several months have elapsed, but there has been no recurrence.

2. Why are no cases reported from Africa? Whether the disease is really unknown in Africa I am not able to say, but none have come to my knowledge.

3. What changes take place, or fail to take place, in the bile to bring about the pale colour of the stools? It was formerly believed that this was due to absence of bile, but chemical examination shows that bile is not absent but is present as leucourobilin, and the gall-bladder contains normal-coloured bile.

4. Are there two distinct classes of sprue? As already mentioned, cases arising in India and some other parts of the East are often associated with an excess of proteid diet and hyperchlorhydria; these are the patients who complain most of a recurrence of symptoms when given food with liquor pancreaticus. Others develop on a fatty diet with organic hyperacidity and hypochlorhydria. Both suffer from dyspeptic and toxæmic symptoms, and so both do well on the calcium and parathyroid treatment, but the latter can take pancreatised food, sometimes at least, and it would appear, therefore, that in both there is intestinal toxæmia with upset of calcium metabolism and parathyroid function, but that in the former there is in addition the endocrine disturbance secondary to pancreatic over-stimulation. If organic acids (and not merely inorganic, as hydrochloric acid) can also bring about excessive production of secretin on entering the duodenum, then this difference vanishes.

It will be of interest to know whether similar felicitous results can be obtained when the treatment is carried out on patients in countries where the disease is endemic.

[1] Van der Scheer states that it does occur in Holland and Germany.

CONGENITAL DISLOCATION OF THE HIP: A NEW APPARATUS.

BY JOHN GILMOUR, M.S. DURH., F.R.C.S. ENG.,
HON. SURGICAL REGISTRAR, ROYAL VICTORIA INFIRMARY ;
HON. ASSISTANT SURGEON, SICK CHILDREN'S
HOSPITAL, NEWCASTLE-ON-TYNE.

IT is the custom at the present time to treat congenital dislocations of the hips, after reduction, by a plaster-of-Paris apparatus. There are objections to this method. In the conduct of a normal case this has to be removed and a fresh plaster applied for each new position into which the hip-joint is brought as the treatment proceeds. Apart from the time and skill required of the surgeon in charge of the case, great care is demanded in the nursing of the child in the intervals. A plaster apparatus is at any time a cloak which hides most effectively all that is underneath, and in the treatment of congenital dislocations of the hips this is undesirable both from the surgeon's point of view and from the mother's. It cannot be said, for instance, that the plaster, when applied, is proof in all cases against subluxations ; for when the inevitable muscular atrophy sets in it is apt, unless frequently inspected and reapplied when necessary, to fit loosely round the joints and to allow room enough for the dislocation to recur.

Nor does the plaster permit of easy radiographic examinations ; on the contrary, it fogs all such procedures, and is most troublesome when it prevents the ready detection of minor degrees of recurring dislocation. From a hygienic point of view it leaves much to be desired. Such plasters are apt to become impregnated with urine or fæcal matter, when they smell, and soften and fray at the edges. I have also known them to harbour lice. The risk of bedsores is real, and ordinary care of the skin is difficult. Massage to the encased limbs is practically impossible, so that as plaster succeeds plaster the limbs shrink more and more, and only a prolonged course of after-massage can restore the tone of the weakened muscles.

With the object of improving these several defects I have tried to replace the plaster apparatus by a mechanical one which would be of use throughout the period of treatment. To be efficient this should (1) be applicable to all the positions required in the treatment of congenital dislocations ; (2) effectively control tendencies to redislocation ; (3) not interfere with X ray examinations ; and (4) permit of easy access to the surface of the limbs for nursing purposes and massage. The appliance consists of a body-frame and two jointed thigh-pieces which fix the lower limbs at the angles required.

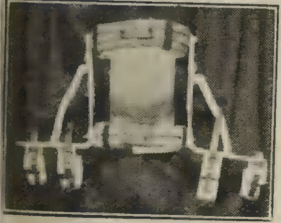

FIG. 1.—Both thigh-pieces fixed at 90° abduction and 90° flexion.

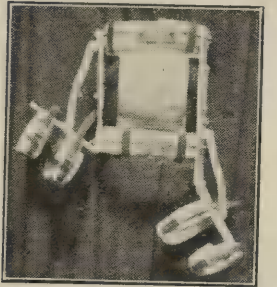

FIG. 2.—Right thigh-piece abducted to 90° and flexed to 50°. Left thigh-piece at 45° abduction and 150° flexion.

Body-frame.—Two light slotted metal bands which encircle the thorax and the pelvis are fixed behind to the upper and lower extremities of two flat metal bars set vertically about 3 inches apart. This constitutes the frame. It is padded to protect the patient from pressure both behind and within the encircling girths, and the pads are covered with leather. Double nuts and screws are used to fix the horizontal bands, and there is always ample room for respiratory movements.

Thigh-pieces.—Each thigh-piece is formed from two bars of metal of equal length to those of the frame, which are united end to end by a simple hinge-joint. The upper bar or arm serves a double function ; it fixes the thigh-piece to the frame and can be moved along the slotted bands of the frame, to which it is fixed by screws and nuts, thus supplying varying degrees of abduction, ranging from 0° when fixed in front, to 90° when fixed at the side. When fixed it also adds to the rigidity of the apparatus. The lower bar or arm bears two leather-covered metal bands which strap on the thigh above and below the mid-point of the femur. Control of the thigh is thus obtained, and by fixing the angle at the hinge-joint the degree of flexion at the hip-joint can be securely maintained.

Two methods of fixing the hinge-joint of the thigh-piece at any angle, from 45° to 180°, are applicable (1) by means of a lattice screw-joint, and (2) by using a cross member. The former is a beautiful piece of mechanism, giving nice adjustments of the angle, but is rather an expensive addition. The latter is simpler and inexpensive, and fulfils all ordinary requirements. It is the method adopted here, and consists of a piece of metal with swinging flanges at each end. One of these is fixed to the centre of the lower bar of the thigh-piece, whilst the upper can be screwed to the upper bar at any point in its length, there being a series of perforations in it through which the screw can be passed. As this end is moved up or down, the angle is diminished or increased. Flexion to correspond with the axillary position is as readily obtained as right-angled flexion or smaller degrees. The patient shown in the illustration has had her right thigh thus fixed, though it is now possible for her to assume an angle of flexion of 80° without subluxation.

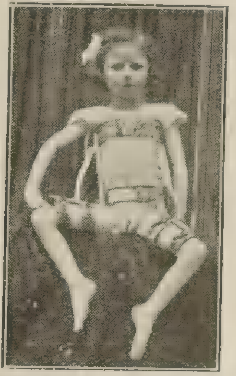

FIG. 3.—The apparatus in place on a patient with double dislocation.

In Fig. 1 both thigh-pieces are fixed at 90° abduction and 90° flexion. In Fig. 2 the right thigh-piece is shown abducted to 90° and flexed to 50°, whilst the left thigh-piece is in a position of 45° abduction and 150° flexion. In Fig. 3 the apparatus is shown on a patient in the Sick Children's Hospital, Newcastle-upon-Tyne, who had a double dislocation and came under treatment when 4½ years old. The left hip gave no trouble ; the right hip showed a constant tendency in plaster to subluxate, but this has now been corrected. It will be noticed that double pieces of metal have been used for the upper arm of the thigh-piece and that the hinge-joint on the left in Figs. 2 and 3 is dropped below that of the right. This is only possible if double bars are used, and is only needful if one hip has to be kept flexed up to less than a right angle longer than the other. The tight structures round the lower part of the highly flexed hip-joint tend to drag the opposite side of the pelvis downwards away from the pelvic band ; consequently also to remove the opposite hip-joint from its true relation to the controlling thigh-piece. By lowering the angle of the hinge to a corresponding degree its distance from the hip-joint is kept constant, and the lower bar retains the thigh at the fullest correction. The apparatus is easy to control ; it is comfortable and cleanly ; it is lighter than plaster as usually applied. Easy access is provided to the child's limbs, and the buttocks and perineal region are left free. It permits of untrammelled radiographic examinations and is moderate in price.

I have to thank Mr. F. G. Hilliard, instrument-maker, Gosforth, Newcastle-on-Tyne, for care and patience taken in making the apparatus.

HIGH BLOOD PRESSURE.[1]

BY E. M. BROCKBANK, M.D. MANCH.,
F.R.C.P. LOND.,
PRESIDENT OF THE MANCHESTER MEDICAL SOCIETY.

BY high blood pressure I mean arterial tension which resisted a pressure equivalent to 160 or more millimetres of mercury before the pulse-wave was obliterated, the normal being 120–140 mm., as estimated by a sphygmomanometer of the arm-band type, or the compact portable little instrument invented by Leonard Hill, which has the great advantage that, being applied only to the anterior surface of the wrists, it does not cause the unpleasant sensations of the band instrument in sensitive women, and it does not induce threatenings, let alone an actual attack, of angina pectoris as an arm-band instrument may do. I am not about to relate any scientific observations, but to give you the chief, if discursive, impressions gained from carefully looking over my notes of the last 160 cases of patients with blood pressure above 160 mm., with and without obvious organic disease; to consider the various, and generally unsatisfactory, methods of treatment; and especially to mention a new form of treatment which is giving encouraging results—namely, diathermy.

My observations have been entirely confined to systolic high pressure. I have taken a pressure of 160 mm. as being abnormal, even for a person of 80, because I do not adopt without qualification the aphorism that the second and third figures in this measurement may be those of a person's age, and yet be normal; in other words, that it is normal for a person of 60 or 80 to have a blood pressure of 160 or 180 respectively and that no danger lies therein.

Is too much Attention given to High Pressure?

Some practitioners think that a great deal too much fuss is made of high blood pressure, and we certainly find it displacing appendicitis in popular literature. If this means that we need pay no attention to high blood pressure in a patient who comes complaining of subjective symptoms, and other symptoms which are objective to us, caused by it I do not agree. If it means that there are some adults of 40 or 50 years of age of either sex, who go about leading ordinary active lives, playing games, and apparently in robust, untirable health with blood-pressure of 160 or more, unknown to themselves or anyone else, and that they have a chance of living their normal expectation of life, I do agree. But there are only a few adults who do this. Although high blood pressure is common in the consulting room, it is only found in a comparatively small number of elderly people over 60 who have never had any symptoms of it in their lives, and in examining supposed healthy people of the commercial classes for insurance I do not believe, judging from my own experience, that one man or woman applicant in 25 has a blood pressure above 140, and certainly not one in 40 has to be refused a policy because of high pressure.

High blood pressure is often found to be present in persons who live an active, untirable life, thinking themselves of robust constitution until an abnormal strain adds some extra foot pounds of labour to a willing but overworked heart, and this long-suffering organ breaks down. To relate one of many instances, a very active gentleman, aged 53, was quite well until October, 1922, when hurrying three-quarters of a mile to catch his train he felt great oppression in the chest, and could hardly get along the last 100 yards. His blood pressure when I examined him some weeks after was 200, and he has never got back to his usual health. I therefore do not look upon high blood pressure as a negligible condition, but one which ought to be recognised as soon as possible and reasonable precautions taken against danger from it. Many a life can be prolonged by such precautions, and the sooner they are taken the better, because the longer the high pressure exists the more difficult it is to deal with it. As I have said, people with high pressure are often untirable in work or exercise. When I read "Wild Sports and Natural History of the Highlands," by Charles St. John, saw what long expeditions he used to make, even tiring his gillies, I wondered what sort of blood pressure he had, and on reading his life I found that, for years, in his 40's, he suffered grievously from occasional violent headaches, and when he was 44 he had a stroke, paralysing the whole of his left side, and that he died three years later. This looks very much like high blood pressure. I always suspect people that I know of as being tireless workers of having high blood pressure, but there are many very busy men who have a perfectly normal pressure.

Heredity.—Unfortunately, none of my patients could tell me whether any of their forbears had suffered from high pressure, but this condition must run in families like many other pathological conditions do. One only could tell me that his father, who died at 85 of a stroke, had it.

Family history, however, has a great influence in prognosis in high blood pressure and expectation of life, as it has in all ailments. I think more and more of its value in life insurance work. High pressure is far from being incompatible with old age. Thus of my 160 cases 22 lived to be over 70. One gentleman of 78 had a pressure of 240. One woman, aged 75, had a pressure of 210. The prospects of life in an adult in the 50's or 60's with high blood pressure are much better, when there is a family history of longevity, than they are when there is a history of death of a parent in the early 50's, especially from apoplexy. To take one example only.

A doctor under 50 with pressure of 190 gave this history. His father was alive last year, aged 82, and mother 74. Three paternal uncles were alive and over 74, a paternal aunt died at 79. His mother's mother died at 93, and her father at 70. Quite recently I examined a man of 65, for insurance, and was instructed to pay particular attention to his circulatory system. His heart was practically normal; his blood pressure was 160, hence the special note from the insurance company, which evidently was not a thick-and-thin believer in higher pressure for older ages. His arterial walls were normal; no albumin or polyuria. A life-long abstainer. There was no indication of high pressure in the family history. Father died aged 73, after an accident. Mother died, aged 56, of cancer; a brother at 44, and another at 61 from unnecessary causes, not pressure, and a sister died at 62 of cancer. I went back to the previous generation, and found his four grandparents had totalled 320 years, all living to about 80. One paternal uncle died at 86, and other uncles or aunts lived to the 70's and 80's. So I advised the office to accept the proposal in spite of the high pressure, and this they did.

A family history of death from apoplexy in the fifties and early sixties is not uncommon. I did not like the prospects of life of a man in the fifties with a blood pressure of 160, who had to lift heavy weights in his business, and whose father died before 60 of a stroke, brought on during a fit of coughing. I had to deal with such a case once.

If the radial artery shows evidence of pathological changes in its walls, or if there is any nephritis present, the outlook is not as good as in those cases, and they form the majority, in which there is no apparent organic disease.

Therefore I do not think high blood pressure is a negligible condition at any time or in any person.

Age Incidence.—I will not trouble you with a lot of statistics, but will merely refer to what interests me from a review of the 160 cases I dealt with. All the cases were seen in private practice and amongst the commercial classes. Fifty-three were in women and 107 in men. The youngest man was 40 years old, and he had no obvious disease; his pressure was 180. The youngest woman was aged 38, and she had no albumin or sugar in the urine. Her blood pressure was 190, and she had a good family history. There were nine men with pressures varying from 160 to 180, of ages between 40 and 45. The oldest man was 76, and his pressure was 180, and the oldest woman was 79, with a pressure of 190. The highest pressure was one of 280, in a woman of 53, and a man of 60. I have measured over 320 in a cotton-mill working woman. Fifty-five of the cases occurred between the years of 50 and 60, 54 between 60 and 70, and 22 between 70 and 80. There is a slight increase in the average pressure of the oldest decade as compared with that of the youngest group—namely, 200 to 180—but not much.

---

[1] Abstract of the Presidential Address delivered before the Manchester Medical Society on Oct. 3rd, 1923.

Symptoms.

I now come to the more important subjective and objective symptoms of high pressure.

Nervous Symptoms.—Complaints referable to the central nervous system are very common—headaches; irritability, sometimes mental changes; transient dizziness or transient blindness coming on at any time, or especially when stooping; epileptiform seizures, either with convulsions or in the petit mal form; "queer bouts" without loss of consciousness, but with inability to move; transient losses of consciousness for a few seconds; pins and needles or a sensation of cold in the limbs and face; sleeplessness, or disturbed sleep; and what is very important, transient and disappearing monoplegia, or aphasia, or even hemiplegia, which clears up almost completely, leaving only a slight local paralysis. One gentleman, after bathing in the sea, had an attack of vomiting, with a complete right hemiplegia. I saw him the same morning, and he had a very high pressure. He improved under treatment, the arm alone being weak in the end. The transient slight paralyses are very interesting, and may occur on and off over a period of two years. I meet with them very rarely in any other cerebral lesion, and then only in senile arterial degeneration. I do not know how they are caused; but Prof. Shaw Dunn and Dr. Core will, I hope, give us their views on this matter. A transient spasm of the blood-vessels of the cortex, if such is possible in high tension, would explain them. Thrombosis of the cerebral vessels would explain them, as it does many cases of cortical-area paralysis which occurs when the blood pressure is low. But whatever causes these transient paralyses, whenever I am told about them I expect to find high pressure and am generally right.

Hæmorrhage from mucous surfaces is common, especially from the nose, hæmorrhoids, or the uterus, and, less commonly, the stomach and intestines, and bladder. Such bleeding acts as a safety-valve, and it is a problem of treatment as to whether that from piles or the uterus should be stopped by operative measures. I have not yet had to stop bleeding from the nose by plugging. One patient, a man over 70, was relieved by profuse bowel hæmorrhage which "flooded the bath-room floor," so his wife said. He undertook more public duties than he ought to have done at his age, and whilst presiding at a public meeting had a hæmorrhage which flooded his ventricles this time, and he died in the infirmary. A lady, aged 38, with pressure of 190, is at her worst before her period begins: then she has menorrhagia for two weeks and relief of symptoms. Epistaxis, as you know, is often alarmingly profuse in these cases, sometimes going on for one and a half to two hours, but not uncommonly no other attack occurs for a couple of years, or indeed for several years—over five in one elderly lady. I am surprised that hæmorrhage does not occur much more frequently. It seems to me to be wonderful how the blood-vessels, especially the small arterioles in the mucous membranes or in the brain, can stand a pressure of 200, or over 300 instead of 120, without bursting, and yet they do in more than half the cases.

Heart.—The heart is always more or less enlarged in chronic high blood pressure, sometimes to twice or three times its normal size. Sometimes the en-argement is slight and very difficult to make out. t may extend into the left axillary region, and I have been astonished on several occasions to see how big it has got without attracting attention. In the early stages it is pure hypertrophy, and then no trouble may arise from the high pressure, but eventually muscle failure will develop and dilatation follow, necessitating a visit to a doctor. Its forcible action may distress the patient, but time and again I have been surprised to find that no discomfort has been felt from the greatly enlarged heart. Valvular disease of the heart was ascertained to be present in only 11 cases, and in most of these it was mitral incompetence. It is surprising that the mitral valve does not dilate more often under the very severe stress it is put to. The blood pressure in all these cases was very high—190 in one case, over 200 in most, and as high as 280 in a man of 60. Slight aortic obstruction was present once only, and naturally I found no case of aortic incompetence, such a condition being incompatible with high blood pressure and life.

Bruit de galop was found in 12 cases, and I look upon this as an indication of cardiac muscle failure and a sign of grave prognosis. At the same time I have been surprised to find how much can be done for people with galop rhythm by judicious digitalis and dilator treatment. Diathermy also assists in their relief. Most of these patients had a blood pressure of over 200.

Auricular fibrillation occurs in a small percentage of cases. It may be merely a coincidence, but as we do not know all the causes of the disturbed contraction of the auricle it is possible that what causes some cases of high pressure may also set up the circus movement of the auricular muscle. It is sometimes very difficult to recognise high pressure by the finger only in auricular fibrillation when the pulse waves are unequal in volume. I have been somewhat surprised to find that the larger beats may resist a pressure from the sphygmomanometer of 200 mm.

Angina pectoris may be the first indication of high pressure. The pain may be slight like indigestion or of the severest nature. It occurred in 22·5 per cent. of men, and 13·5 of women, in my series almost twice as often in men, which is not surprising when we remember that the exciting causes of anginal pain in high blood pressure is overworking an abnormal circulatory apparatus, and business men are more likely to do this than women. Two of the women also led very active lives, both of them managing and serving in a butcher's shop, which is very hard work.

Albuminuria in my experience is more often absent than present in high tension. I ask all cases of high pressure if there is any nocturnal polyuria or the regular necessity to pass water two or three times in the night with the idea that if there is it means that there is deficient secretory capacity on the part of the kidneys from chronic disease which makes them unable to excrete all the urea in the daytime, and requires them to work overtime at night to clear up arrears. In asking for this symptom, care must be taken to discount the effect in the night's excretion of urine of a tumblerful of milk or water, taken just before bedtime, which generally only causes one disturbance of sleep.

Is it Advisable to Reduce High Blood Pressure?

The question is often asked, Is it advisable to try and reduce high blood pressure? My answer to this is that it depends on the personal and family history. If the high pressure is causing symptoms which send the subject of them to the doctor, and if there is a family history of early death from causes attributable to high blood pressure, such as apoplexy, an attempt must be made to reduce it; but if there are no symptoms and the condition is only found accidentally, and if there is a history of longevity, I should not attempt to reduce it; merely give some general advice as to diet, and avoidance of conditions likely to increase the already high pressure. Some patients are not comfortable if the pressure they have been used to for years is reduced materially. In between these two extremes are cases which must be dealt with on their own special indications for treatment.

Treatment.

We must warn the patient about the dangers of hurried exertion and excitement without alarming him, and advise him to lead a careful, quiet life. He should not necessarily give up his business, and he may even play mild golf when the pressure is not above 160 or 170, and there is a good family history. Some mental occupation to keep their minds off their symptoms is good for these people, and many business men have no hobby to turn to if they retire. If the successful Lancashire man's maxim can be brought into practical application so much the better—organise, deputise, supervise—supervision or consultation occupies a man without hard work. It allows of easier hours, and does not require daily attendance at the office if he does not feel quite fit for it, and that is a very great deal in prolonging life. All public work, especially if exacting or liable to work up excitement in contentious debates on councils, lay, or church, and all rush engagements must be given up. Exposure to cold and walking against strong winds should be avoided. The lives of many people with high pressure are like what John Hunter said his own was: "At any person's mercy," and the excitement of angry controversy may cut them short suddenly as it did John Hunter's, though I do not know that the latter had high pressure as well as mitral stenosis and atheromatous coronary arteries.

Remove Possible Causes.—It is necessary to remove any abnormal condition which may be lowering vitality or producing subjective or objective signs of disease. One very common condition is oral sepsis, such as pyorrhœa alveolaris, deep-seated suppuration at the roots of teeth, especially crowned teeth, or receding gums. Whenever I suspect sepsis I have the teeth examined by X rays. One man had broken down with ill-health of uncertain origin. I found a pressure of 190, and as he had receding gums I had an X ray examination made, and three dentists advised removal of all the teeth. This was done in the early part of the year. Two months later the pressure was 150 mm. only, and the man was back at his work, and is now doing the full work of a busy lawyer.

Eyestrain may be a contributing cause of high blood pressure, and whenever I suspect it I have the eyes examined by a specialist. Eyestrain can do much harm and make chronic invalids of people, but that is another story, and I will not go into it here.

Our treatment of high blood pressure is greatly handicapped by our ignorance of the real cause in the great majority of cases—that is, in those with no organic disease. I will pass over the treatment of those cases which are associated with chronic nephritis and arterio-sclerosis, and they form the minority, after merely saying that they must be dealt with on general lines of treatment of these diseases, with special attention to any symptoms calling for relief. A great difficulty is our imperfect knowledge of the interactions of the secretions of the ductless glands on the functions of each other, and especially on the suprarenal bodies. We have learned a great deal lately about ductless glands and activating bodies, but as it ever is, the more we get to know, the more we find there still is to know. The nature and mode of action of the secretions of ductless glands and of activating substances is still but an opening book with many of its leaves stuck together. If one ductless gland goes sick it does not supply the full amount of secretion that is probably necessary for the production of the secretion of the other glands, and the whole balance of work is upset. As we do not know which gland is at fault, it is difficult to tell which of them to give, to restore the balance. Polyvalent glandular pharmacy or a dose of therapeutic grapeshot, though of use in a few cases, is not as helpful as we should like it to be.

Diet.—I really doubt whether special forms of food play much part in producing high tension, but I advise a minimum consumption of butcher's meat and of coffee or tea. A man who habitually over-eats and over-drinks himself at breakfast, lunch, and dinner is more likely to develop high tension than a person who is temperate. Uncooked apples are good because they take up room, satisfy the appetite, and have no vices. Other fruit and plenty of green vegetables, cooked or in salads, are good. I generally tell people to eat in moderation plain substantial food which they know suits them. I do not consider that one glass of good sound very light wine, red or white, at the meals, or a glass of whisky at present-day strength at night does any harm, nor does tobacco in moderation. It does no good in the long run to cut a man off all the little comforts.

The nitrite group of drugs relaxes spasm of involuntary muscle and reduces arterial tension more or less, but generally less than more, and only temporarily, in high blood pressure. I never know how these drugs will act. I have seen excellent results follow the administration of a mixture containing a grain and a half of each of the iodides of potassium and sodium, and a grain or two of nitrite of sodium. Sodium nitrite is, however, an unstable compound, and likely to be inert unless obtained at the best chemist's shops. Therefore I often use one or two drops of liquor trinitini in place of it. Erythrol tetranitrate acts for a longer time than sodium nitrite. A good tablet containing sodium nitrite, erythrol tetranitrate, manitol nitrite acts best of all and is stable; it also is not as objectionable as many patients find the nitrite mixture to be. I should say that some patients find any nitrite treatment unpleasant. Some physicians recommend a $\frac{1}{4}$ gr. of calomel three times in the day for the first three days of each week. Others, a draught of 10 gr. of potassium nitrate with 20 of potassium bicarbonate in a tumblerful of water first thing in the morning. It is a good plan to secure a watery examination of the bowels each day by a saline aperient.

Artificial bleeding by venesection relieves tension temporarily, but it is necessary to remove a pint or two according to the bulk of the patient. Perhaps we do not remove enough, for I believe that if some natural bleedings from the nose, which I have seen going on for a couple of hours, had been measured they would have amounted to more. Wet cupping is futile; one patient had his life made miserable by doing this to himself monthly on the advice of a French doctor.

Iodine in the form of iodide of potash, but especially in oily or albuminoid combination or in colloidal form, is often very effective in high blood pressure. It is my stock drug for high pressure with or without arterio-sclerosis. I am sure I have used it many times with success in people over 60 years of age who complain of dizzy attacks, aphasia, or transient paralyses, and I believe its administration for years to be of much value in older people whose blood-vessels are getting atheromatous. It may act by preventing the blocking of arteries or by promoting absorption of any degenerative changes already present, or it may act by making good a deficient supply of iodine resulting from defective thyroid secretion. I do not know how it acts, nor do I care; but on the principle that it often does good and does no harm I use it, and with much success in chosen cases. When given in oily combination it rarely causes iodism as the potash compound does, even in people very susceptible to the action of the latter.

Digitalis.—I use digitalis in all these cases of high blood pressure which show signs of cardiac muscle failure—namely, anginal pain, shortness of breath, dilatation of the heart, and gallop rhythm. The heart very often is greatly enlarged—to twice or three times its normal size—and it often has a gallop rhythm. Digitalis in the form of a granule of 1/240 gr. digitoxin, or a tablet of digifolin (which contains the watery soluble constituents of $1\frac{1}{2}$ gr. of digitalis leaves and is rapidly excreted) given every morning is most useful. I have been surprised at the good results obtained for a time at any rate. It is a disputed point as to whether digitalis increases arterial tension in men. Pharmacologists say it does not. Clinically I have never known it do so, and it does help the failing heart.

In *anginal* cases we must help the overworked heart by digitalis. All patients with high pressure, but anginal cases especially, must avoid all opportunities of hurry, flurry, and worry, dress warmly in winter, take light substantial meals, avoid flatulence, and keep the bowels open, and they may live for years. Anyone with anginal pain of any degree should avoid over-eating, and should take time over meals, rising with an appetite rather than feeling that too much has been eaten. In my experience this applies especially to breakfast, for several patients have complained of the pain in the chest and shortness of breath coming on when hurrying to catch the train in the morning.

Surgical operations are often called for in subjects of high pressure, and the danger from a general anæsthetic naturally arises. Hæmorrhoids, not necessarily caused by the high pressure, not uncommonly occur and bleed—and in my opinion they should not be removed unless they cause discomfort from their size and position or become painful. Bleeding from the rectum is one of the simplest and cleanest of nature's safety valves. It generally occurs only when the bowels are opened, and the patient is all the better for it. I am doubtful whether curetting for metrorrhagia in high pressure cases does any permanent good. Chloroform and ether as general anæsthetics reduce blood pressure, and I have never heard of apoplexy taking place during their administration, and there must be scores of people with high pressure who are anæsthetised by their means. Nitrous oxide is, however, dangerous, and cases of apoplexy are recorded from time to time during its use. The extraction of several teeth under a general anæsthetic does no harm to the patient; on the contrary, the blood letting entailed by it will be of benefit.

Diathermy in Treatment of High Pressure.

I now come to the real genesis of this communication—namely, the use of diathermy in treatment of high pressure. In my opinion this gives better general results than drugs do. I read in various contributions to medical literature of its value, and you will probably have seen an account of a discussion on the subject at the recent annual meeting of the British Medical Association, in which various observers—Cumberbatch, Humphris, Turrell—relate their own successful experiences. I have now tried it for over a year in a dozen cases, and in all there has been improvement with more or less permanent relief of symptoms and lowering of pressure. Dr. Cowan, who has treated the cases for me, will speak on its value and mode of application. All the patients, with or without obvious organic disease of the kidneys or cardiovascular system, felt better, and some of the latter continued with it at their own request after I wished to discontinue its use, as the pressure was not materially reduced. Diathermy has given encouraging results in some of my cases of angina pectoris, associated with high blood pressure and over-strain of the heart muscle. Nagelschmidt has watched diathermy treatment over some years and recommends it for angina pectoris. I give some iodine preparation night and morning in most of the cases, and digitalis when necessary.

I can give you no more satisfying evidence on the value of diathermy than the experience of a doctor patient of mine, who wrote thus to me as recently as Sept. 20th: "You will remember you took my blood pressure 18 months ago and found it 190. I have been having diathermy for nine months and the pressure has come down to 150. I have the treatment at two months' intervals and it keeps the pressure down."

Medical Societies.

MANCHESTER MEDICAL SOCIETY.

A MEETING of this Society was held on Oct. 3rd, when Dr. E. M. BROCKBANK, the President, read an address on

High Blood Pressure.

He said that it had been the custom of the Society for the President to occupy the whole of one meeting with an address, but he felt he could make the consideration of this large and difficult subject more attractive if other members were to coöperate with him in addressing the meeting. He proposed himself to deal with the clinical aspects of persisting high blood pressure, Prof. Shaw Dunn would discuss the pathological side of the question, Dr. Donald Core would speak on its nervous manifestations, Dr. John Cowan on its electrical treatment, and Dr. McSwiney would describe the investigations which are being carried out in the electrocardiograph department of the Royal Infirmary on the effect of age and disease on the rate of the pulse wave. Dr. Brockbank's remarks will be found in another column of this issue of THE LANCET.

Discussion.

Prof. J. SHAW DUNN, in discussing the morbid anatomy of cases of high blood pressure, stated that it was only in a minority of cases that the kidneys showed a chronic nephritis. In the majority the kidneys, though they might be diminished in size, revealed no certain evidence of old inflammatory changes on histological examination. In these non-nephritic cases death might be due to some intercurrent disease, but if it was dependent on the hypertonus it usually occurred either from cerebral hæmorrhage or from failure of compensation of an overloaded heart. Generally speaking, in cases of hypertonus dying from cerebral hæmorrhage there was more predominant degenerative disease of arteries, more atrophic kidneys, and the left ventricle showed pure hypertrophy. Where death in hypertonus occurred from cardiac failure the arteries, though thickened, showed less degenerative disease, the kidneys were of normal size or larger than normal, and the heart was very greatly enlarged, showing hypertrophy and dilatation of both ventricles. Referring to the transient nervous seizures described by Dr. Brockbank, Prof. Dunn mentioned that it was not uncommon in cases of high pressure to find small areas of softening, especially in the basal nuclei in the brain; these were probably the result of spasm or narrowing of arterioles, and might account for the seizures in question.

Dr. DONALD CORE said: I shall only have time to touch upon certain points of neurological interest in high blood pressure. The organic change most constantly associated with a high blood pressure is the cerebral anæmia of cerebral atheroma, and in such cases the readings may be very high. The type of patient is known to all: they are, usually, vivid, eager, energetic old people, discursive and young-looking for their age, and when the condition becomes of clinical importance they complain of pain somewhere about the body, impairment of concentration power and emotional control, with defective sleep, and a tendency towards depression. Arteriospasm is liable to occur in such people, and for the most part the blood pressure in such cases is high. At the same time this does not necessarily obtain, and I have records of at least eight cases in which the systolic blood pressures vary between 120 mm. and 168 mm. The value of one solitary record of the systolic blood pressure is open to criticism, unless the reading is excessively high or excessively low. Some years ago the importance of the correlation of the pulse-rate with the blood pressure reading was emphasised, and I am convinced that the greatest value from blood pressure readings is obtained when the daily variation in a systolic pressure is charted and compared with a chart of the daily pulse-rate. A systolic blood pressure of 160 mm. with a pulse of 120 need not necessarily have the same implication as a blood-pressure reading of 160 mm. with a pulse of 60. In cases of both cerebral hæmorrhage and cerebral thrombosis the blood pressure is liable to be high, but in the former case the pulse-rate is, as a rule, slow, whereas in the latter it tends to be quick.

Functional Disabilities.—The problem of an abnormal blood pressure is of especial interest in certain so-called functional disabilities of the nervous system. It is obvious, of course, that a raised blood pressure may be conservative, or a protective measure on the part of the body in response to certain organic diseases especially affecting the kidneys. Equally certainly, ductless gland deficiencies may be responsible for abnormally low readings. In organically healthy people the height of the blood pressure would appear to vary directly with the degree of emotional control that the particular individual has brought to bear upon his normally experienced emotional tones, or, in other words, we may look upon normal blood pressure, whatever that may be, as representing, in the absence of disease, normal emotional control for the man who is normal for his community; and in the absence of organic disease, variations above and below this would appear to go with exercise and disuse of this control respectively. In old people, people who are anxious, and people exposed to dread, the blood pressure, other things being equal, tends to be high. In young people, in obtrusively hysterical patients, and in a large group of epileptics, the blood pressure does not tend to be high, unless some complication be present. Many years ago, Sir Maurice Craig quoted observations of interest in this connexion, showing that the blood pressure is raised in cases of melancholia, and is not raised in cases of mania, but that in melancholia with agitation it tends to be rather on the low than the high side of the normal. This amounts to saying that restrained, carefully-guarded behaviour is, in the long run, associated with a raised blood pressure, whereas, the reverse obtains in uncontrolled freedom of behaviour. In this respect it is obvious that the blood pressure in healthy people presents certain interesting analogies to the psycho-galvanic response. A further point arises from the consideration of the above statements, and that is this, that the duration of symptoms in organic disease is liable to be associated with a raised blood pressure in proportion to the dread and anxiety associated with the course of the case, and in excess of what might be considered normal from the standpoint of the pathological state. Abnormally high blood-pressure readings in the absence of organic disease are associated essentially with pain, for the most part of vascular origin, impairment of the power of concentration, depression and disordered sleep, whereas, abnormally low blood pressure, possibly associated with a ductless gland deficiency, is liable to be accompanied by morbid sensations other than pain (particularly "altered consistency" sensations in different regions of the body) with very considerable impairment of emotional control. The President has already referred to certain methods of treatment of raised blood pressure, and I understand that Dr. Cowan will also deal with this point. I may say, however, that the drastic reduction of high blood pressure is in many cases likely to be associated with more discomfort than would be the case had it been left alone, and unless the reading is excessively high, in many cases it would be better to take measures to prevent the blood pressure becoming higher than to bring it down to any extent.

Dr. John Cowan spoke on the

Diathermic Treatment of High Blood Pressure.

He said: There are two ways in which diathermic currents can be applied: (1) hand-to-hand and foot-to-foot method; (2) condenser couch. I have chiefly used the former method. In this method the current is passed through the upper part of the body from one hand to the other; afterwards it is passed through the lower part of the body from foot to foot. I give 20 minutes for each half of the body. During the treatment the patient feels only a sensation of warmth. I have found no difference in the results whether the patient sits up or lies down. Usually I treat weakly patients and those with known heart affections lying down; the others I treat sitting up in a chair. Altogether I have treated 38 cases, and in every case a fall in blood pressure has been obtained. In cases with arterio-sclerosis or albumin in the urine the pressure has quickly risen again. These cases require treatments about once a week to keep the pressure down. High blood-pressure cases without either of these two conditions do very well, and the pressure remains down; in one of my patients it has remained down after 12 months. In one of these cases only was the result not maintained. The amount of reduction obtained at each sitting has varied from 5 mm. to 70 mm. All cases have what I call the "irreducible minimum" below which the pressure will not remain. If the pressure is carried below this point it quickly rises until this point is reached. In my cases this point has varied between 120 mm. and 180 mm. The number of treatments required to reach the "irreducible minimum" has been from three to ten; they are given at three or four day intervals. My conclusions are that: (1) Age and sex appear to play no part except that in old people more treatments are required. (2) No diminution in the secretion of urine has been observed in any case. (3) Symptoms improve—viz., headaches, breathlessness, insomnia, fleeting pains, anginal pains, vertigo; some angina pectoris cases have improved very well. (4) Bruit de galop in one case disappeared after the first treatment. (5) The pulse appears to alter in character; from being a sharp impulse sometimes approaching the water-hammer type it becomes more in the nature of a heave and apparently more prolonged.

Dr. B. A. McSwiney spoke on the velocity of the pulse-wave in relation to age and to elasticity of the arterial wall. He showed how the pulse-wave is recorded by the Hill[1] hot-wire sphygmograph. The carotid and radial pulses are recorded simultaneously and the velocity of the pulse-wave calculated from the findings. The relation of pulse velocity to age was pointed out. If the formula of Bramwell and Hill[2] $\frac{12\cdot7}{(\text{velocity of pulse-wave})\ 2}$ is used, 12·7 being a constant, the elasticity of the arterial wall can be calculated. Between the age of 10 and 60 the elasticity of the arterial wall is halved, which accounts for the increase in pulse pressure and systolic blood pressure with age (Bramwell, Hill, and McSwiney).[3] The relation of the velocity of the pulse-wave and of the elasticity of the artery to varying diastolic pressures is studied by applying a sphygmomanometer bandage to the arm and applying pressure as shown by Bramwell, McDowall, and McSwiney.[4] If P is the pressure inside the artery and p the applied pressure then P–p is the effective pressure. The carotid and radial pulses are recorded simultaneously at different effective pressures, and the velocity of the pulse-wave under the bandage calculated from the results. If the formula mentioned above is applied a curve of the elasticity of the arterial wall can be plotted. This method enabled one to compare the condition of the artery in the same individual at different times, or to compare the result obtained from one individual to the average result.

ROYAL SOCIETY OF MEDICINE.

SECTION OF THERAPEUTICS AND PHARMACOLOGY.

A MEETING of this section was held on Oct. 9th, Sir **WILLIAM HALE-WHITE** in the chair. Prof. **A. J. CLARK** was elected President of the section for the present year.

Prof. **HUGH MACLEAN** opened a discussion on the

Use of Insulin in General Practice.

The paper appeared in full in last week's issue of THE LANCET.

Dr. **GEORGE GRAHAM** said that there was no doubt of the great value of insulin in the treatment of diabetes. It must, however, be remembered that insulin was not a substitute for dietetic treatment. He had heard of a doctor who complained of the lack of result of treatment with insulin, whilst his patient was continuing to eat his usual quantities of bread and potatoes. He agreed with Prof. MacLean that insulin treatment was for the wise, and not for the foolish, doctor and patient alike. Coming to the question as to the best way of using insulin, F. G. Banting and F. N. Allen and their colleagues believed that it should be employed to render the blood-sugar normal in the fasting state. Certain observers in the United States thought the clinical condition more important. When insulin was used principally for the improvement of that condition the patients certainly felt better, but their blood-sugar often remained nearly as high as it was before treatment. From the point of view of the islands of Langerhans they were no better. Jocelyn took up an intermediate position, holding that the urine should be sugar-free, but that the blood-sugar might be allowed to remain slightly raised. He himself thought that the patient should be so treated that the blood-sugar became normal. (The speaker then showed illustrative blood-sugar charts.) He had treated some 40 patients in all; of 23 serious cases 19 left hospital with normal blood-sugar. Unless one waited a long time some people probably could not attain to the normal. Of the four patients who left hospital with their blood-sugar still raised, one died and the other three were much improved. Of the total of 40, 2 died, 1 of pneumonia, this patient's blood-sugar having reached normal, and the other of undiagnosed tuberculosis of the lungs.

Necessity for Short Treatment and Large Dosage.

Since beginning treatment with insulin he had altered his method, although the aim remained unaltered. With many patients, as had already been said, the blood-sugar would come down if one waited long enough, but a rush of cases necessitated a shorter time for treatment of each individual case; he therefore increased the dosage, until one woman received daily 60 units in the morning and 20 units in the evening. For such large doses patients should be n a hospital or nursing home. Except in such an nstitution they should not receive big doses until they were able to recognise the symptoms of overdosage. When patients showed these symptoms the dosage was reduced, the night dose—which, personally, he preferred to make the smaller one—being reduced first. It was not difficult to bring the blood-sugar down to normal, but it was more difficult to know what to do when it had been brought down. He delayed giving carbohydrates until this had happened, withholding bread as long as possible in order to give the islands of Langerhans a chance of attaining some degree of recovery. With regard to the later reduction of dosage, one of his patients was now receiving 40 units ess, and another 35 units less, than when they left hospital, and both were much better. With patients n a state of coma four or five hours, and with severe ases of diabetes five or six weeks, gave the answer as o whether insulin treatment was of use, but mild ases would necessitate waiting for years before results. He was now under-working the islands of Langerhans by withholding carbohydrates in these early cases. With reference to Prof. MacLean's statement as to the giving of a dose of sugar in cases of renal glycosuria, the majority of such cases that he had seen always passed sugar.

Prof. **J. J. R. MACLEOD** expressed himself as unable to talk of the clinical aspect of insulin. He had been much interested in the words of the two previous speakers with regard to the use of small quantities. Although it might not be possible with very small quantities to produce much change in the disease, the patient often felt very much better as a result of their administration. Experiments had been done to measure the "glucose equivalent" of insulin—i.e., the amount of glucose that each unit of insulin could cause to be metabolised. Some of his colleagues had tried to determine the glucose equivalent in certain "pedigree patients"—patients with definite diabetic history carefully controlled and dependable for observations of this type. The glucose equivalent did not remain constant at different times in the same patient. Whatever might be the reason of this variability it was obviously important. The clinician dealt with patients not entirely depancreatised, whose island tissue was not completely degenerated; this tissue would sometimes react with endogenous production of insulin and sometimes would not react. Work had therefore been carried out with depancreatised dogs incapable of producing endogenous insulin.

Experiments with Depancreatised Dogs.

It was found that when a dog was secreting quantities of sugar, insulin had a greater effect than when the secretion was smaller. The results on different days were more constant than those obtained with human patients, and results obtained with different animals were very close. In one series of experiments the amount of glucose, and in another series the amount of insulin, given per diem was constant. The results showed that there was some relationship between the amount of glucose which could be metabolised and the ratio between insulin and available glucose. It would be of value to have a patient treated with as small a quantity of insulin as would increase his ability to metabolise carbohydrates and make just the difference necessary to bring him into a healthy state. In many diabetics the subjective symptoms were more distressing than the objective symptoms; insulin seemed to improve these cases. Coming to the question as to whether it was worth while trying to obtain insulin which might be taken by the gastro-intestinal tract or by inunction, Campbell and others had tried this with encouraging results. He believed that insulin might be useful for the treatment of milder forms of diabetes. It had been found that in diabetics the average glucose equivalent was something under 2; in dogs the lowest value was over 3, but he believed there was no essential difference. A diabetic patient was deriving about 6 per cent. of his carbohydrates from proteins; this form of carbohydrate was not the same as carbohydrate introduced as such. The dogs derived their carbohydrates from sucrose, which might explain the difference in the glucose equivalents. As regards the ultimate effect of pancreatectomy, it had been found possible to keep a dog alive for four months, but no longer; the reason for this was not known.

Skin Irritation: Level of Blood-Sugar.

A good deal has been said in Canada, in the United States, and over here about skin irritation as a result of insulin treatment. Insulin preparations always contained some protein; the pancreas of both ox and pig was used, and it was found that a patient who experienced irritation from insulin made from the one might have none with insulin made from the other. Two or three such cases had occurred in Toronto. This skin irritation might discourage a patient, and it was worth while to change the type of insulin used. He would not give a definite answer as to whether a patient should be given enough insulin to keep the blood-sugar normal, or should be allowed to carry a certain load of glycosuria; but he thought it safer to keep the blood-sugar at the normal level. Enough information was not yet available to enable it to be said that an excess of blood-sugar was a physiological condition.

Toronto Scheme for Training of General Practitioner.

As to whether the general practitioner should feel qualified to undertake the serious treatment of diabetes with insulin, in Toronto it was decided that it would not be advisable to encourage this undertaking until the practitioner had had a short period of instruction in the use of the remedy. Through the Ontario Medical Association an arrangement had been made whereby each week 40 general practitioners spent two days in Prof. Graham's clinic in the Toronto General Hospital where lectures were delivered and clinical opportunities afforded, so that they might see exactly what the results of insulin treatment were. Hence no serious accidents in America had arisen from the use of insulin by the general practitioner. The Ontario Government had now provided, through the agency of the Provincial Health Board, that all these physicians should have insulin for the treatment of patients unable to afford it otherwise. This public health expenditure had been considered legitimate, and thereby insulin would have a fair trial. It would certainly be risky for a medical practitioner without easy access to those familiar with diabetes and insulin to undertake the treatment without occasional observations of the blood-sugar. Personally, he would not care to be responsible for treatment with this very powerful hormone without the chance of seeing what was happening by means of examination of the blood-sugar. Every patient in Toronto was deliberately given a big dose of insulin to acquaint him with the symptoms of hypoglycæmia. It had been noted that in a case with marked diuresis insulin had removed the diabetes but not the diuresis: this point deserved attention. As regards the use of adrenalin, it was well to remember that the latter might not act in removing the symptoms of hypoglycæmia unless there was a store of glycogen in the liver; such a store would certainly be found in a healthy individual, or in a diabetic patient treated for some time with insulin, but might not be found in a case of acute diabetes. This point should be watched, and an intravenous injection of glucose given in the acute case that came into hospital in a state of coma.

The Importance of Blood-Sugar Estimation.

Dr. E. P. Poulton re-stated the problem of insulin treatment in general practice as follows: Did they aim to keep the blood-sugar normal, or did it matter if the patient was passing a trace of sugar? He thought it better, if possible, to get the blood-sugar within normal limits. Could this be done in general practice without doing blood-sugars? He thought so, if they would be content to go slowly. After sugar had disappeared from the urine there was still a large margin before the approach of symptoms. The latter might, however, appear before the blood-sugar was sufficiently low, but the body would become used to the treatment, and the blood-sugar would gradually fall. He had experimented fairly satisfactorily, without doing blood-sugars, but the doctor must be experienced who attempted to do so. Concerning diet, he considered it better not to give starch; he gave 5 per cent. of vegetables—30 or 40 g. per diem. The patient felt happy with this amount of vegetable food, even without bread. Prof. MacLean had stated that the only unsuitable cases for insulin treatment were cases of renal glycosuria; these, however, were not cases of diabetes mellitus at all. He was inclined to agree. It was remarkable how elderly people improved and kept sugar-free. The problem of separating off the cases of renal glycosuria from those of diabetes mellitus must, however, come down to the blood-sugar curve. In the treatment of coma, he usually gave 40 units, perhaps at intervals of four to six hours, and every specimen of urine was tested. Queer results were sometimes obtained; patients came round to some extent and then died. He suggested that coma was a mixed uræmic and diabetic condition.

Reply.

Prof. MacLean, replying, said that there was some slight misapprehension of his attitude. He had at one time said that it would be better if the general practitioner in using insulin were to keep some sugar in the urine; he did not wish at that time to say anything rash, but treatment had now passed beyond that stage. What was the normal blood-sugar? It varied up and down after each meal, between 0·09 and 0·13 or 0·14. There must be some reason for that variation. He had simply wished to ensure safety. He felt that there was virtual agreement between all the speakers that the urine should now be freed from sugar, and that the blood-sugar should be brought within its normal variations. If the general practitioner took trouble he could safely treat cases without doing blood-sugars.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

The annual meeting of this association was held on Oct. 9th at the Elizabeth Garrett Anderson Hospital, when Dr. Louisa Martindale, the retiring President, called attention to the satisfactory annual report, read by Dr. Kate Platt, the hon. secretary, and then vacated the chair to her successor, Miss Chadburn, M.D.

Before proceeding to give her address, Dr. Chadburn, the new President, discussed briefly some of the points raised by Sir Humphry Rolleston in his recent address at the London School of Medicine for Women. Sir Humphry Rolleston had suggested that women work too hard and play too little. Dr. Chadburn believed that as students, women played well and worked well; but that as young medical women starting their permanent work in life, they did not work hard enough—not as hard as the young man in the same position. Medical men did not always help women to achieve and maintain a high standard of work; they were, she thought, too apt to praise work done by women which they would have torn to shreds if it had come from a man. Men and women were specialists of a sort by virtue of their sex alone, and where this sort of specialist was needed neither could take the place of the other. On occasion there was required that complete confidence and understanding which could only come from a member of the same sex. Dr. Chadburn expressed her conviction that the supply of medical women never would equal the demand—the supply was bound to be limited, the demand was rapidly increasing. That more women applied for resident posts than could get them was no proof that all these women are not needed in practice. As to the question of genius in women, even were it rare, this would not alter the value of the average merely talented worker who was perhaps more necessary in the world of work than those with genius. Another point raised had been that of marriage. It was true that marriage accounted for serious depletion of the ranks of medical women, and, moreover, quite apart from the gaps in work due to actual child-bearing, marriage and a family could not but take energy and time and interest *from* work which the unmarried woman could give *to* work. On the other hand, married women's work had a value all its own, and no one but the woman herself should decide whether she should continue work or not. Some women patients, some men needing advice about their wives, would choose a married woman, as they might under other circumstances choose a married man. As to the effect of menstruation on professional efficiency, Dr. Chadburn pointed out that medical men see only the pathological side of menstruation, since the normal does not present itself to them. Dysmenorrhœa and menorrhagia were not normal. She maintained that a large proportion of women, perhaps over 90 per cent., have no discomfort of any sort at the period; of the rest, only a very small proportion suffer to any (even mildly) incapacitating degree—these cases are pathological. People were too apt to talk as if every woman had dysmenorrhœa. The leaflet drawn up as a result of a discussion at the Medical Officers of Schools Association by Dr. Alice Clow, and distributed amongst mistresses and parents, gave sound advice, emphasising the fact that the monthly period is not a malady but a natural function; that exercise should be continued throughout the period, and that discomfort amounting to pain was a pathological condition for which a doctor should be consulted. The President admitted that there existed a relatively small number of women with more and less incapacitating dysmenorrhœa: these women, if incurable, were unsuitable for a profession which makes severe demand for exacting service at all and any hours, day or night. This was a disability almost as serious as being minus one arm or one leg, or being subjects of heart disease or epilepsy. Men and women with serious disabilities must take them into consideration in choosing their work in life.

The President proceeded to give an address wherein she surveyed the diseases of the large bowel from cæcum to anus, which had fallen to her care during the years 1905–1922, excluding pressure effects on the bowel from outside; also cases of adhesions and their sequelæ, diseases of the appendix, hæmorrhoids, fissure, fistula, and complete perineal tears. In spite of strenuous efforts it had been found difficult to trace cases, but it was encouraging to find a few cases of carcinoma of rectum, sigmoid, colon, and cæcum living as long as eight to 14 years after radical excision. Special points were: The incidence of disease in the large bowel, the great preponderance of malignant disease, of the malignant cases the large proportion of cases inoperable when first seen and the advanced stage of those that were operable, and the rarity of the discovery of malignant disease of the large bowel at an early stage. The incidence of disease in 181 hospital cases taken consecutively: Cæcum, 12 (carcinoma 7, tubercle 3, intussusception 2); colon, 13 (carcinoma 12, tubercle 1); sigmoid, 32 (carcinoma 22, colitis 6, ulcerative colitis 1, perforation of chronic ulcer 3); rectum, 121 (carcinoma 80, fibrous stricture 16; of these 16 syphilis accounted for 10, cellulitis for 3, tubercle for 3); constriction with no ulceration 4 (cancer of cervix 1, old cellulitis 2, imperforate anus 1); radium ulcer following prophylactic radium treatment 1, shallow ulcers (?) cause 2, proctitis 2, villous tumour 4, prolapse 5, fæcal impaction 4, spasm of rectum causing obstruction with fæcal vomiting 1. Of the 181 cases 121 were carcinomata, of which 62 were operable when first seen. The President did not believe that any more radical operation than the modern abdomino-perineal excision for rectal cases would be possible; she considered that operations on the large bowel can be as radical as is physically possible. Advance must be sought either in obtaining cases earlier for treatment, in some treatment other than operative, or in prevention. Early diagnosis seemed the most hopeful means of improving results, but unfortunately the onset was insidious. Exploratory abdominal section for diagnostic purposes had not yielded much success in the President's hands.

Results of Operation.—Dr. Chadburn's operation results for carcinoma as far as available were as follows (the cause of death, unless stated, is unknown):—

Cæcum (7 cases): 5 operable, all 5 quite well, seen recently, the operations being 20 months, two years, six years, nine years, and ten years ago.

Ascending colon (2): 1 died on fourth day after operation; 1 well after two years; at a recent hysterectomy on this patient no sign of recurrence inside the abdomen was seen.

Transverse colon (1): died two years later.

Splenic flexure (1): died one year later from recurrence, kidney and lung.

Sigmoid (8): 3 well (three years, eight years, and a few months after operation); 3 dead (two to four years after); 1 no report; 1 died sixth day after operation.

Rectum: 45 operable cases.

Abdomino-perineal excision (31): 7 died from operation, 24 recovered (13 without colostomy, 11 with colostomy). Of the 24 cases which recovered abdomino-perineal excision 8 sent no report; 4 are reported to have died in three months to three years; 1 died 3½ years after operation from acute septicæmia, no signs being found of recurrence of carcinoma; 11 have been seen, 1 has recurrence in the vagina, 10 have no signs of recurrence, 1 case after nine years, 2 cases after eight years, 4 cases after four to five years, 3 cases after two to three years.

Recto-colostomy (2): both recovered, well five and eight years after operation.

Perineal excision (11): 2 died from operation; 9 recovered, 1 well 14 years after operation, 8 no report.

Local excision (polyp found on section to be malignant): 1 died from bronchitis.

The President concluded that the operations for carcinoma in the large bowel are borne well, especially in early cases, those cases that died from operation in her series were almost without exception very advanced cases, a large proportion of them had more than the affected bowel removed—e.g., in three cases she had to remove the uterus and part of the vagina, in one the left ovary and tube and an adherent portion of small intestine in order to remove a rectal growth; in another case she had to remove the left kidney and ureter because of the involvement of the ureter in a growth of the sigmoid colon. As regards technique, she performed lateral anastomosis of bowel, or an end-to-side anastomosis as being safer, easier, and less likely to contract than an end-to-end anastomosis. For rectal carcinoma an abdomino-perineal excision, if possible, was the operation of election, with or without colostomy. Where the vessels of the sigmoid loop and the position of the growth allowed, she brought the sigmoid to the anus, leaving the sphincter after incising it, to secure drainage of the bowel. These patients had a very fair and in some cases a very good control. A perineal excision, though not the operation of election, could be a very free one if approached by the vaginal route. Dr. Chadburn did not think there was ever any advantage in taking away a portion of the sacrum—as good a clearance of glands could be obtained without, but not nearly as good a clearance as by the abdomino-perineal route, where the inferior mesenteric artery and the glands on it were removed at the highest possible point. She concluded her address by giving details of certain unusual cases.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—The first meeting of the sixty-eighth session was held in the board room of the Miller General Hospital, Greenwich, on Oct. 12th. The President, Dr. W. H. Payne, occupied the chair. Dr. E. P. Cumberbatch, Mr. Willmott Evans, Mr. C. A. Joll, Dr. H. Pritchard, and Dr. H. Nockolds showed clinical cases. On Nov. 9th Dr. Hildred Carlill will discuss Tabes Dorsalis, and on Dec. 14th Sir Thomas Horder will speak on Carcinomatosis. A clinical evening will be held on Jan. 11th. On Feb. 8th Mr. Kenneth M. Walker will speak on Experimental Work on the Internal Secretion of the Testis, and Rejuvenation Operations. On March 14th Mr. Montague L. Hine will read a paper on the Interdependence of Ophthalmology and General Medicine, and on April 11th Mr. Percival P. Cole will deal with the Surgery of the Face and Jaws.

CANCER CONGRESS IN BRUSSELS.—The *Ligue Nationale Belge* against cancer, which has recently been created, has decided to hold a congress on this subject on Nov. 18th, 19th, and 20th in Brussels. The committee engaged in the organisation of this congress hope to gain the collaboration of all branches of medical science in the social aspect of the campaign against cancer, and an attempt will be made to interest practitioners in recent therapeutic advances, as well as in the scientific study of the genesis of this disease. The representatives of allied and friendly countries will be welcomed at this congress, the first two days of which will be devoted to a discussion of biological and therapeutic problems related to malignant disease. At the end of the congress there will be a demonstration of the radio-therapeutic establishments in Brussels. All inquiries and communications should be addressed to La Ligue Nationale Belge, 80, rue de Livourne, Bruxelles.

Reviews and Notices of Books.

SERIES OF SURGICAL MONOGRAPHS.

Reconstructive Surgery of the Upper Extremity. By ARTHUR STEINDLER, M.D., F.A.C.S., Professor of Orthopædic Surgery, Iowa State University Medical School. London and New York: D. Appleton and Co. 1923. With 50 plates. Pp. 310+xix. (Series of Surgical Monographs, £6 5*s.* the set.)

Dr. Steindler's book on the "Reconstructive Surgery of the Upper Extremity" forms a part of the series of surgical monographs which are appearing under the editorial supervision of Prof. Dean Lewis, Dr. Eugene Pool, and Prof. Elting. In his preface the author tells us that the book is written as a record of personal experience rather than as a text-book, and that therefore it does not pretend to deal exhaustively with the subject as defined in the title. It appears, therefore, as if another work might be required to fill up the gaps, and that a whole library would be required for adequate discussion of the reconstructive surgery of the human body. However, the very fact of its limitation to personal experience makes this monograph of special value. As Dr. Osgood says in his introduction, "This is the type of book we need . . . the conclusions of a thoughtful man who believes his experience in a limited field has taught him certain things which it is his duty to pass on to his colaborers (sic) in the art of healing." It is characteristic that on the vexed question of birth palsy the author passes no judgment on the different theories of causation, but contents himself with the practical results of treatment. To show the scope of this work it will be enough to give a list of the chapter headings: Subacromial bursitis, congenital deformities of shoulder, paralysis of shoulder and elbow, the paralytic hand contractions of wrist and fingers, spastic paralysis, tuberculosis, chronic arthritis, congenital malformations and deformities, traumatic deformities, and the physiotherapy of the upper extremity. A perusal of this list will show how much is lacking to a complete presentment of diseases of this region, but as far as it goes it is up to date and the author's personal experience is frankly and clearly stated and statistics given in full.

The book is fully illustrated with photographs and diagrams, and handsomely printed and got up. Despite the numerous plates there are hardly any pictures of apparatus, which are of such importance in the treatment of deformities. Especially noticeable is the absence of illustrations of the technique of plaster-of-Paris appliances.

Gastro-Enteroptosis. By ROBERT C. COFFEY, M.D., F.A.C.S., Surgeon-in-Chief, Portland Surgical Hospital. Same publishers and series. 1923. Pp. 303.

ONE of the most difficult problems for the clinician is the appreciation of the legitimate place surgery should assume in the treatment of gastro-enteroptosis. Most unfortunately, surgery of this condition has been hindered by over-enthusiastic workers. The selection of suitable cases is probably more important in treating this disease than almost any other, and rules have not yet been satisfactorily worked out by which we can choose cases which will benefit by surgery. Dr. Coffey in this very valuable monograph puts forward what is known of the several aspects of this question. He has reviewed the literature very completely and presents the subject in a conservative manner. He writes in the preface: "I concede that in bringing forward this subject of ptosis and stasis, we are opening one of the most dangerous fields for surgical powers that has ever been open to the surgical 'confidence man' who needs no other excuse for performing a surgical operation, than the consent of the patient." He issues a warning, too, about X ray observations. These are of "inestimable value in the study of these cases, but are the most dangerous agent yet placed at the disposal of the unscrupulous surgeon, because they are so evident to the laity and at the same time so meaningless when considered independently in the history of the case, and not properly interpreted."

It will be seen from these different statements that the author is very cautious in his recommendations. He views the subject more from the anatomical than the physiological side. He shows how the weight of the upper abdominal organs is supported very largely by the psoas shelf; how in certain individuals this shelf is inadequate as a supporting structure, owing to the formation of the spine; how enteroptosis depends to a very large extent on whether the normal peritoneal fusions have taken place during embryonic life. He divides visceroptosis into general abdominal ptosis, right-sided ptosis, and mid-line ptosis, and whatever may be the origin of the dropping of the viscera, he is convinced that once displaced, the abdominal bands, which are regarded as the defence of the organism against further falling of the viscera, give rise to many abdominal symptoms. He concludes, and he is supported by clinical experience, that the simple division of such bands can only give very temporary relief, the bands re-forming as strongly as ever. His treatment is based on the proper fixation of the dropped viscera and division of the bands, which do not re-form when the viscera remain in their normal positions. The details of treatment are very clear and the citation of cases is rather convincing. Whether underlying physiological causes have been thrust too much into the background is open to debate. The author's views have not crystallised sufficiently for him to give rules based on radiographic appearances, as to which cases should receive surgical and which medical treatment. This question must be settled by future investigators. His views may be summed up in one of his concluding sentences. "Being a mechanical and physical condition largely, mechanical and physical measures are essential to its proper treatment." As the result of experience, he says unhesitatingly that no part of his surgical work has been more satisfactory than that pertaining to the ptosis question.

Traumatic Shock. By WALTER B. CANNON, A.M., M.D., late Lieut.-Colonel, Medical Corps, U.S. Army, George Higginson Professor of Physiology, Medical School, Harvard University. Same publishers and series. 1923. Pp. 201.

A TREATISE on surgical shock from the pen of one of the best all-round physiologists in America, and one who has studied the subject in the field as well as in the laboratory, in association with British investigators, cannot fail to be of value and interest to English readers. After carefully stating exactly what he understands by the term "shock," the author proceeds to a physiological analysis of the condition, and, like other physiologists, is of the opinion that the condition is primarily due to concentration and stagnation of blood in the capillaries. Some of the consequences of this are then considered, and, after a full discussion of the various theories which have been advanced to explain the causation of shock, the book concludes with an account of the various forms of treatment which have been advocated. The book is sound and well written, and provides solid ground for further investigations into this important condition.

Surgery of the Spleen. By EUGENE H. POOL, M.D., Attending Surgeon, New York Hospital; Clinical Professor of Surgery, Columbia University; and RALPH G. STILLMAN, M.D., Clinical Pathologist, New York Hospital; Assistant Professor of Clinical Pathology, Cornell Medical School. Same publishers and series. 1923. Pp. 347.

THE surgery of the spleen is in reality a small subject and is yet in its infancy. This depends largely upon our lack of knowledge of the functions of the spleen in normal life. In this volume we find a very good epitome of what is known of splenic activity both in health and disease. A wide range of literature has been consulted and the views of different observers are put forward with well-balanced judgment. After a review of the anatomy, embryology, physiology, and pathology of the spleen, the clinical features associated with splenic disease are treated in separate chapters. The obscure diseases of the spleen are set forth as far as present knowledge allows, and surgical indications are given. The book ends with a chapter on operative procedures. The monograph will be useful as presenting present-day knowledge of diseases associated with the spleen.

The Transplantation of Tissues. By HAROLD NEUHOF, M.D., Instructor in Surgery, Columbia University, Associate Surgeon, Mount Sinai Hospital. Same publishers and series. 1923. Pp. 297.

THE knowledge relating to the transplantation of tissues is far from exact, although a great deal of work has been done and the literature is extensive. Too often unwarranted deductions have been made from experiments by enthusiastic workers, whilst there has frequently been an absence of controls. A service has therefore been performed by Dr. Neuhof in making a critical and comprehensive review of a subject to which he has personally devoted much study. After a consideration of general principles and of the factors necessary to success in the different forms of transplantation, the grafting of the different tissues is described, and the indications for such methods are set forth. Throughout the author insists that the evidence for survival of moderate-sized growths of any tissue is of the slightest. This is true of autoplastic grafts where the prospect of success is greatest. He believes that a study of blood compatibility may possibly render homo-transplantation a practical measure. He reports one success where tatooed skin was transplanted to a patient of the same blood group. He believes that skin grafting could be used more extensively with benefit to patients. Technique for different operations is described. The inlay method for curing ectropion and other defects is not considered, though it is the best available for certain purposes. The chapter on fascial grafts is informative and helpful to the plastic surgeon. The author is commendably cautious in extolling the virtues of such transplantation. Always he insists that an attached flap is better than the free flap which, is only to be employed when local plastic measures are impracticable. It is this caution manifest throughout the book which renders his recommendations for the use of transplantation methods so valuable. He shows how fascia lata can be used for the cure of ptosis, the improvement of facial paralysis, the repair of defects in dura mater or abdominal wall, and for other purposes. As a covering for bone ends in arthroplasty he does not believe free grafts to be suitable. The chapters on fat and bone grafting provide a mass of useful information. We gather that the use of fat as a free transplant could be extended. Cartilage is stated to resist disintegration longer than bone. It is regarded as the best material for the closure of skull defects and as a support in the fashioning of a new nose. There is a critical review of work that has been done on the transplantation of whole organs.

This is a book which any surgeon would be glad to possess for consultation when the problems of plastic surgery arise.

ANÆSTHETICS.

Practical Local Anæsthesia. By ROBERT EMMETT FARR, M.D., Minneapolis. London: Henry Kimpton. 1923. With 219 engravings and 16 plates. Pp. 529. 42*s*.

THE dedication of this book "to that important individual, the patient, who, fate has decreed, must undergo surgical treatment" gives a true line to one of its most noticeable characteristics, the constant sympathy of the author for the trials of the patient. This quality is especially important on the part of one who practises local anæsthesia. It has saved Dr. Farr, ardent partisan though he is of local methods, from ignoring their inevitable occasional inadequacy. When the respective advantages and disadvantages of local and general methods are contrasted, Dr. Farr never loses sight of the patient's feelings. His remarks, however, on general anæsthetics are the least valuable portion of his work. The book is divided into three parts, and the first part deals, in addition to general anæsthetics, with equipment and technique, a description of the sensory nervous system being added. The especial importance of technique and of correctly designed instruments, as a part of the essential devices for avoiding pain, are well enforced by the author. The lesson is instilled throughout that under local emergencies success is impossible unless the surgeon constantly exercises the utmost gentleness. Thus the patient is spared the amount of injury which is apt to be inflicted without noticeable harm at the moment by those who operate only during general anæsthesia.

The second part describes the use of local anæsthesia in all regions of the body except the abdomen. This is reserved for the third part. Many of those who use local anæsthetics for most purposes fight shy of them for operations on the upper abdomen. Dr. Farr is not one of these. He makes frequent use of splanchnic anæsthesia by the anterior route, having opened the abdomen under infiltration anæsthesia. The relative values of regional and infiltration methods are fully discussed and the reasons for generally preferring the latter are clearly demonstrated. The usual solution that the author prefers is novocaine between 0·07 and 1 per cent. with epinephrin. The latter ingredient he reduces to a very small proportion when operating for exophthalmic goitre. In all operations about the anus and in tonsillectomies he uses 1 to 600 solution of quinine and urea hydrochloride, after operating under novocaine, in order to prevent after-pain. An official term new to us appears in the book—the "psycho-anæsthetist." He, or more often apparently she, is capable of giving general anæsthetics when they become necessary and the decision on this rests largely with him or her. Apart from this, the psycho-anæsthetist supplies moral support to the patient, both before operation and at the time, and in various ways ensures that calmness of the mental atmosphere on which Dr. Farr so rightly lays stress in local anæsthesia. The author employs preliminary hypodermic injections in moderation only, and rightly distinguishes between the use of local anæsthetics on persons already stupefied with narcotics and their employment as the responsible anæsthetic agent.

The illustrations are very good, and the whole book, with its careful attention to detail, will prove of great assistance to any surgeon who proposes to become expert in the use of local anæsthetics.

The Art of Anæsthesia. Third edition. By P. J. FLAGG, M.D. London and Philadelphia: J. B. Lippincott. 1923. With 136 illustrations. Pp. 371. 18*s*.

THE third edition of Dr. Flagg's book has increased in size but not unduly. The author's work on discriminating degrees of cyanosis is perhaps the most interesting of the new matter. He rightly attaches the utmost importance to the colour of the blood as a clinical index of condition in the patient under anæsthetics. Hence to be able to gauge accurately slight differences in blood colour should be a potent means of safety in the anæsthetist's hands. The differences depend, of course, on differences in oxygen content. For using this symptom to estimate a patient's condition, Dr. Flagg has employed an instrument called the "hæmoxometer" or "oxyhæmoglobinometer," which affords, he says, a simple means of reading the oxygen content of the blood. Dr. Flagg expresses a pronounced preference for gas and oxygen and ether with preliminary hypodermics as the best all-round method thus far devised. He is impressed with the possibilities of danger and of failure with gas and oxygen alone and disapproves of the saturation method. A chapter is devoted to the duties of the nurse before, during, and after anæsthesia. In this country, at least, she has little part to play before and during anæsthesia so far as the anæsthetic is concerned, but her duties afterwards, as detailed by Dr. Flagg, might well be carried out by many nurses "on this side."

Elements of Pharmacy, Materia Medica, and Therapeutics.

Eleventh edition. By Sir William Whitla, M.P., M.D., D.Sc., Emeritus Professor of Materia Medica and Therapeutics, Queen's University, Belfast. London: Baillière, Tindall, and Cox. 1923. Pp. 672. 10*s*. 6*d*.

The new edition runs on the lines of the old; it is the best book of reference for ordinary drugs, official and non-official. As there has been no new British Pharmacopœia since the last edition, the official part is changed very little, but in the non-official remedies there are several additions and omissions. Drugs come and go, and Prof. Whitla gives them a fair chance. The appearance of a drug in this volume is a hall-mark with which the maker may well be content. While the new edition brings one up to date it is worth keeping the old edition to look up preparations which have had their day. Only a few points need comment: we are astonished there is not more reference to quinidine, which is still left as the uninteresting sister of quinine and is classed as one of the drugs that are less frequently employed than formerly. Acriflavine, yadil, eusol, and iodex now find a well-deserved place, and gamboge reappears after a period of exile. Hay fever vaccine now replaces serum. The list of vaccines and serums is a specially useful one, for the knowledge and doses of these is such that no one can carry them in his head. Reference in this book is always easy, for the index is excellent.

Sewerage.

The Designing, Constructing, and Maintaining of Sewerage Systems and Sewage Treatment Plans. Ninth edition. By A. Prescott Folwell, Past President of the American Society for Municipal Improvements. London: Chapman and Hall, Ltd. Pp. 477. 27*s*.

The established reputation of this work by an American expert obviates the necessity for elaborate review, as does also the fact that general principles as to sewerage systems and sewage disposal interest the medical profession rather than the scientific and practical details here given. The work is divided into two parts. The first part on sewerage systems comprises 13 chapters dealing with the amount of house sewage and of storm sewage, with flow in sewers, flushing and ventilation, collection of data, designing, specifications, construction, and maintenance. In the second part relating to sewage disposal, the first chapter deals with disposal by dilution; then follow chapters on the removal of suspended matters, oxidation methods, and other treatment methods.

The subject is clearly dealt with, and numerous figures make specially difficult points clear. In an appendix is given a list of the processes adopted in a large number of cities in America.

JOURNALS.

Journal of Pathology and Bacteriology. Vol. XXVI. No. 4. Pp. 433–556. October, 1923.—The Organisms of the Fowl Typhoid Group, by R. St. John-Brooks and Mabel Rhodes. A study of the various organisms which have been isolated in Europe and America from fowls and other birds with dysenteric symptoms and described under a variety of names. Some of these are shown to be synonymous, and the grouping of the species is clarified. The paper is a good example of the valuable taxonomic work which the existence of the National Collection of Type Cultures at the Lister Institute renders possible. —Vitamins and Bacterial Growth, by G. A. Wyon. There has been a good deal of loose talk about the influence of vitamins on the growth of bacteria; the author shows that vitamin B from yeast exerts no favourable action, and incidentally that amino-acids are not such important adjuvants as has been supposed.—Diphtheria Toxin Production on Douglas's Medium, by A. F. Watson and U. Wallace. Tryptic digests of meat, prepared under controlled conditions of time and temperature, make it possible to obtain high-grade diphtheria toxins with considerable certainty.—The Structure of the Thyroid Organ in Man, by G. Scott Williamson and I. H. Pearse.—The Healing of a Uterine Wound: Mitosis in Unstriped Muscle, by D. McIntyre. The occurrence of reparative cell-multiplication in human plain muscle is quite exceptional.—Primary Liver-cell Adenoma (Hepatoma), by A. F. B. Shaw. A detailed description of one of these interesting liver tumours in a boy of 13. —The Relation of Deprivation of Vitamin B to Body Temperature and Bacterial Infection, by G. M. Findlay. We comment on this paper in a leading article.—On the Composition of *B. welchii* Toxin, by H. Henry. The bacillus produces two toxins, with special actions on red blood corpuscles and muscle respectively. Their relative proportions are the same in different preparations, and hence the neutralising value of antitoxic sera can be ascertained by titrating the hæmolysin in vitro.—The Pathogenesis of Primary Pneumococcal Peritonitis, by J. E. McCartney. The disease is confined to female children, mostly of the poorer classes. Infection takes place through the vagina, and is encouraged by dirtiness leading to a vulvo-vaginitis from which virulent pneumococci may be isolated.—The Presence of Heterophile Antigen in Bacteria, with Special Reference to Shiga's Dysentery Bacillus, by T. Iijima. The organs of certain animals—e.g., guinea-pig but not man—injected into rabbits lead to the production of hæmolytic immune body for sheep corpuscles. Shiga's dysentery bacillus does the same, and some of the toxic effects of Shiga vaccines may be anaphylactic in character, since human serum sometimes contains considerable quantities of heterophile (Forssman) antibody. Cholera, typhoid, paratyphoid, and Gaertner bacilli do not contain the antigen.—Cutaneous Hypersensitiveness in Enteric Infections, with Special Reference to Carriers, by W. McKendrick. Intradermal injections of dilute emulsions of typhoid and paratyphoid bacilli are a valuable method of detecting the persistence of infection in typhoid convalescents and of finding carriers. A positive reaction is highly specific, a negative one of less value. —A Neuroblastoma of the Thoracic Cavity, by J. A. Anderson and T. Shennan.—Leucocytosis in Myeloid Leukæmia, by A. Piney. Hourly counts show a very large digestion leucocytosis, in which all varieties of cells participate about equally; the reaction fails towards the end of life.—A photograph of a group of 98 pathologists, with a key to their identification, forms an interesting record of the last meeting of the Society.

Indian Journal of Medical Research. Vol. II., No. 1, 1923.—This number contains 22 articles.—R. McCarrison contributes a long paper on the pathogenesis of deficiency disease.—J. A. Sinton describes Indian species of the genus phlebotomus.—J. A. Cruickshank and his collaborators write on the statistics of filariasis and the relationship between it and elephantiasis.—J. F. Caius and K. S. Mkaskar have investigated the relationship between the chemical composition of anthelmintics and their therapeutic values.—W. F. Harvey has three articles upon vaccines and laboratory technique; two of these are in collaboration with K. R. K. Iyengar.—H. E. Shortt describes the pathology of acute experimental kala-azar in monkeys; he also has a second short, but important, communication on the recovery of the Leishman-Donovan body from the urine in this disease.—P. J. Barraud writes at length on the revision of the culicine mosquitoes of India.—R. B. Lloyd, E. Muir, and G. C. Mitra have investigated the Wassermann reaction in leprosy, and appear to have settled this question.—E. Muir has studied the spread of leprosy throughout the body, while E. S. Phipson describes an outbreak of typhus in Simla, in which he found the Weil-Felix reaction of very distinct value.

THE LANCET.

LONDON: SATURDAY, OCTOBER 20, 1923.

MEDICAL BENEFIT UNDER THE NATIONAL INSURANCE ACT.

As we go to press, the Conference of representatives of the Local Medical and Panel Committees—to give the body its full name—is sitting in circumstances so familiar to all that they need not be recapitulated further than in the following sentences. The Government has decided to reduce the capitation fee, and the offer published in THE LANCET last week contains their terms in a succinct statement. The Insurance Acts Committee of the British Medical Association have replied categorically to the offer of the Government, pointing out that their answer embodies the advice which they are prepared to offer to the representatives of the two committees at the Conference. The gist of that advice was that the terms offered by the Minister, being inadequate, should be made the subject of arbitration. To the letter of the Insurance Acts Committee the Minister has replied refusing arbitration. This letter will be found on p. 898, together with the reply of the committee acknowledging the responsibility placed upon them, and pointing out that the medical profession cannot accept the position of being placed under the dominance or control of a particular section—namely, the approved societies. With the representatives at the Panel Conference—to use the abbreviated title of the body now in conclave—rests the decision as to what definite reply shall be made to the offer of the Government. From much comment in the public press, and from knowledge acquired here of the feelings of the medical profession, we gather that the machinery for regulating medical benefit under the National Insurance Acts is not widely understood, so that the delays preliminary to the arrival of definite decisions are viewed with impatience, while the appearance is given of subterfuge or hesitation by the constant employment of the phrase that the final responsibility does not rest with this or that body or lie in this or that direction. As the decisions of the representatives of the two committees, arrived at by the Conference, will be the subject of close and wide discussion, it may be useful to set out the structure and responsibilities of bodies concerned in the regulation of medical benefit.

The first thing that it is necessary to remember is that Parliament is supreme both in the interpretation of doubtful points under which any statutory bodies are constituted and in the allotment of the duties and responsibilities of those bodies. Section 8, paragraph 1, of the 1911 Act sets out succinctly the benefits conferred by the Act upon insured persons. They are medical treatment and attendance, including the provision of proper and sufficient medicines and such medical and surgical appliances as may be prescribed by the regulations of the Ministry of Health, now and here replacing the Insurance Commissioners. Other sub-headings of the section include mention of assistance in cases of disease and incapacity, of disablement, and as maternity benefit. Section 14 of the Act deals with the administration by the approved societies and, in the case of those who are not members of one of these bodies, by the Ministry of Health. The following Section (15) in the second sub-clause defines panel practice, setting out how the medical practitioners are expected to meet the situation of administering the medical benefits under the insurance committees, whose duty it is to make arrangements with the practitioners in accordance with the regulations of the Ministry of Health. These insurance committees, as defined in Section 59 of the 1911 Act, are statutory bodies, constituted for every county and county borough. Three-fifths of each committee consists of representatives of the approved societies, the remaining two-fifths being made up of the State, county, and the medical representatives. The Conference which is now proceeding arises in this way. Under the 1911 Act there were created the local medical committees, elected by the medical practitioners in the neighbourhood, whether accepting the responsibilities of the panel or no. The local panel committees, statutory bodies created by the 1913 Act, are chosen by the panel practitioners and the practical result has been that these two bodies proved largely identical. So it has been frequently found simpler for one body by common agreement to function as representing both, and it is these committees who are sending representatives to the Conference. As, however, there is no onus upon them in the Act to choose representatives or to hold a conference, their action is spontaneous. None the less these conferences have been held since 1913, and since 1915 their recommendations have been recognised by the Ministry of Health as coming from a central mouthpiece. After the Conference the representatives deliver their message through the Insurance Acts Committee of the British Medical Association. It is clear that they might choose an executive committee from among themselves and act through that executive committee, and it has been pointed out that in principle this is what should have been done. We do not think that this point has the importance which it assumes in some minds, seeing that the overwhelming majority of the Insurance Acts Committee have been directly elected by the local medical and panel committees. The Insurance Acts Committee will receive the message of the Conference and deliver it to the Ministry of Health, that Ministry having now definitely assumed all the functions of the original Commissioners; and the Minister of Health will decide upon the actual course to be taken obtaining, of course, Parliamentary sanction for his action.

The reply of the Insurance Acts Committee to the offer of the Minister of Health, though temperate and well-considered, has not escaped abuse from the approved society officials. One of these officials has gone so far as to say that the societies are not prepared to agree to such an offer, and further, that the Minister has no right or power to make it. The position taken up by the society officials is that which might have been expected after the expedient had been adopted at the end of 1921 in respect of the surplus funds of the societies. The medical benefit fund is an integral part of the general insurance funds and quite distinct from the sickness benefit funds which are disbursed by the societies. The danger of conceding the principle that the doctors are paid out of the funds of the societies is obvious, for already it is contended that if the doctors are to be paid adequately the weekly payments of the sick insured person must be curtailed. The question is wider than that of an additional shilling or so on the capitation fee, and we therefore regret the decision of the Minister of Health not to proceed to arbitration. We do not want a repetition of the "battle of the clubs."

VITAMINS, INFECTION AND BODY TEMPERATURE.

THE importance of vitamin deficiencies in promoting morbidity and mortality from infectious conditions has often been urged in recent years. Their real rôle in this respect can be determined only by the massive data of hygienic studies, for effects which are substantial enough in the returns of medical officers of health are often outside the practicable range of experimental investigation. It would, for example, be difficult to reproduce and analyse in the laboratory a reduction of infantile mortality from 100 to 80 per thousand births. But the belief that moderate vitamin defects are responsible for a definite increase of infections is much encouraged by the demonstration that, under the exaggerated conditions of experimental work, animals fed on grossly defective diets are found to be much more susceptible to infection by inoculation than are similar animals normally fed. In the last number of the *Journal of Pathology and Bacteriology* Dr. G. M. FINDLAY describes a series of experiments on pigeons deprived of vitamin B, and shows that after a deprivation of two or three weeks they readily succumb to inoculation with the pneumococcus and the meningococcus to which they are naturally completely resistant, and are much more than normally susceptible to doses of *B. coli* and Gaertner's bacillus. Getting an indication of an explanation of this difference from the work of STROUSE on the natural immunity of birds to the pneumococcus, he shows that the vitamin defect leads to a considerable lowering of body temperature, that the effect of any one inoculation can be predicted from the temperature of the bird at the time, and that artificial lowering of temperature with the drug pyramidon induces a similar susceptibility. The same facts have been described independently by C. H. WERKMAN.[1] Under the conditions of these experiments a marked fall of body temperature has a 100 per cent. effect; it is at least not unlikely that smaller deviations from the normal level of heat will have results important enough in the scale of human morbidity.

It is 45 years since PASTEUR, JOUBERT, and CHAMBERLAND found that cooling a chicken made it susceptible to anthrax infection, and enough importance has perhaps not been given since to that classical observation. Fever is now rightly regarded as an important part of the defence against infection; more attention should perhaps be given to subnormal temperatures as aiding infection and depressing resistance. A gay and buoyant temperament and the kind of life it leads to are well-recognised enemies of bacteria; a depressed and meagre existence is on their side. The form of the daily curve of body temperature depends largely on bodily activity; getting up and dressing brings it up to "normal" from the 97° F. or thereabouts which it is at the moment of waking, but its progress to the 100° or so which it reaches at midday is a question of vigour and muscular activity. The mean temperature of the melancholy, ill-fed or lethargic will, therefore, presumably be lower than that of the cheerful and lively. Violent muscular work raises temperature still further, hence perhaps some of the beneficial effects of exercise, but if it is pushed to exhaustion temperature soon falls to subnormal, and the ill-effect of tiredness on infections is notorious.

The mechanism of the relation between temperature and resistance is not quite obvious. With pneumococcus infections the fever is higher than the organism bears easily; it can be shown outside the body that the organism grows better at lower temperatures. But in many cases this does not apply. If the processes of attack by the bacteria and those of defence by the body had the same temperature coefficient, the relation of the two would not be altered by a change. It may be that the coefficients are different, or, which is more likely, that while the attack depends essentially on a single factor—the growth of the organisms—the defence uses a variety of methods, such as antibody production and phagocytosis, which are not directly dependent on one another, and whose combined effect varies with their product rather than their sum. If this be so, changes of temperature make much more difference to the body than to the organisms, which is the same as saying that the temperature coefficients are en masse different.

ECONOMICAL PRESCRIBING ABROAD AND AT HOME.

A STUDENT trained in hospitals where medicines are ordered and appear at request can have but little idea of the prices of remedies, especially as the prescriptions ordered in hospitals are mainly those of stock mixtures prepared with a view to economy. When he first starts in general practice, he is usually over-generous with drugs, in a subconscious attempt to protect the patient from any deficiencies in treatment that may arise through his own lack of experience. Later he finds that his drug bill is too large and he strives to modify it, but gets little help in his efforts apart from friendly hints from colleagues.

The rapid changes in money value in Germany and Austria have necessitated an even more drastic survey of the drugs in use than is necessary in this country. Dr. A. FRÖHLICH and Dr. R. WASICKY[1] have recently pointed out how drugs can be prescribed economically and in what form they can best be given. The information must be especially useful to the young practitioner, for whom the book forms an epitome of practical therapeutics. On the continent fluid medicines are ordered by weight and not by volume, as in this country, and, as a lesson in economy, it is interesting to read that the practitioner is recommended to order codeine phosphate 0·05 aq. dest., ad 200·0, in preference to the same drug made up aq. dest. 200·0. The latter brings the medicine above the 200 gramme limit and so will be charged more heavily than the former. Some of the general rules for economical prescribing are worth noting. Home drugs are to be preferred to foreign ones, tablets to powders and mixtures, and solid preparations to fluid ones; the use of medicines given in drop form is to be limited; infusions and decoctions of non-poisonous drugs should be made by the patient at home; tap-water is generally as good as distilled water; in external medicines alcohol can usually be eliminated and in liniments can be replaced by ammonia; pills should only be used when the active substance forms the greatest part of the pill mass; proprietary preparations should only be prescribed on exceptional occasions and patented names should be replaced by chemical ones. Another publication[2] contains an extraordinary amount of information on everything to do with the practical aspects of drugs; a feature is that the cost of all drugs mentioned is given, and two sections on cheap and dear drugs are included. The prices must be somewhat indefinite owing to the uncertainty of the mark, but the idea is excellent. It is carried further by the frequent references from expensive drugs under proprietary designation to the cheaper form of the same under its scientific or non-patented name. A certain number of prescriptions in this part will help the beginner, and practical notes on treatment are given. Prof. C. Bachem, of Bonn, treats[3] the subject rather differently. This book directs the doctor who has some knowledge of theoretical pharmacology to use the right drug in the right place and in the right manner. Experimental pharmacology has in the past been separated and treated too far apart from practical medicine, and the author's aim is to bridge the gap for the practitioner by treating of different diseases and functions of the body and by bringing together and describing the drugs used for them. This therapeutic arrangement entails the duplicating of some drugs and a considerable amount of cross reference. The drugs are well and clearly described. Proprietary preparations naturally occupy a large portion of the book, and many of those described are little used in English-speaking countries, but this adds to the value of the book, for those commonly used in this country can easily be found in English books. The index of the firms which manufacture the drugs, unobtrusively placed in the book, may be of great use. The author believes that as proprietary preparations abound, there is a demand for information about their composition and contents; for in the battle against quackery and swindling the doctor must possess and impart information on their nature and value in the interests of the public and the manufacturers alike.

Annotations.

"Ne quid nimis."

MEDICAL HISTORY OF THE WAR.

We reviewed last week four large and carefully edited volumes on the Medical Services of the War in the domain of pathology and hygiene, together with the second volume on Diseases of the War. A detailed estimate of the many and varied fields which such work covers cannot possibly be made in the space at our disposal. Taking it as a whole, these volumes make most interesting and informatory reading, and in compiling an official document of the growth of medical science in the forcing house of war, the editors are to be congratulated on accomplishing a great and laborious task. These records have been evidently designed to be read as a comprehensive and consecutive study rather than as a series of monographs, and in this the system adopted of grouping the contributions with the contributors in an index at the beginning of each volume, while leaving individual chapters unsigned, helps very considerably. The reader feels that he is getting a connected story (in many parts one might almost say "romance") bearing the stamp of editorial authority in its balance and general treatment of the subject, and which is at the same time scientifically accurate in details. This sense of editorial responsibility in the reader's mind greatly enhances the value of the work as an authentic history. Also in many places this history must become a valuable work of reference, and for such a purpose it is equally well constructed. The student in any particular section can refer to the author of it merely by consulting the list at the head of the volume, while a full bibliography appended to each chapter furnishes a comprehensive reference to the bulk of the medical literature of the war.

In a general survey of medical experience there are perhaps two facts which claim attention as being essentially lessons of the war. The first is the discovery of the inadequacy of accepted theories of antisepsis in dealing with wounds under war conditions. It was found that the control of sepsis under civil conditions was a very different problem from the prevention of suppuration in wounds where satisfactory primary treatment was often delayed for days. Sir Alfred Keogh makes the striking statement that at the beginning of the war "we went straight back into all the septic infections of the Middle Ages." In recognising the part played by the body fluids, as apart from antiseptics, in overcoming infection, and in devising means to facilitate this action, pathology, chiefly through the investigations of Sir Almroth Wright and his fellow-workers made a great step forwards. The other outstanding fact brought home by the modern conditions of warfare is the paramount importance of hygiene in conserving life and promoting efficiency. It was realised from the first that in a campaign involving millions of men the way to success lay in sanitation. The results of the work done in maintaining the general health and efficiency of the fighting forces and of the civil population under the severest conditions will remain as a benefit to humanity; in a fuller appreciation of the meaning of economy and in the widespread awakening of a "sanitary consciousness" we learned a lesson in the war which can well be adapted to times of peace. As a military text-book, the Medical History of the War will occupy a prominent place, and will form, in the unfortunate event of some future warfare in any part of the world, the basis of sound medical administration. The books are well printed and on the whole the illustrations are good, but the binding is at the best fair. Volumes intended largely for reference should at least be strongly backed, which these are not. The tooling is poor, and their appearance in a library—for they should be on every medical man's top bookshelf—can hardly be called handsome.

THE BLOOD IN SMALL-POX.

Prof. W. H. Hoffmann,[1] of Habana in Cuba, where an epidemic has been prevalent for three years, has examined the blood in 300 cases of small-pox, and has come to the following conclusions. (1) The total number of leucocytes is subnormal during the first three days, amounting only to 4–6000. It rapidly rises after the fourth day, and between the ninth and fourteenth days shows an average count of 17,000, in some cases as much as 30–40,000. In the third week there is an average leucocytosis of 10–12,000, and occasionally 24,000. During the next three weeks the number of leucocytes gradually falls, but still remains fairly high—viz., 9–12,000. Prof. Hoffmann was unable to pursue his observations beyond the sixth week, by which time the leucocyte count had not yet become normal. (2) The differential count shows considerable variations from the normal. The number of polymorphonuclears is diminished in the first week, being on the average 20–30 per cent., and in some cases only 12 per cent. Subsequently the polymorphonuclears remain at about 40 per cent. until the end of the sixth week. There is a considerable increase in the eosinophils, which in the first three weeks number 3–10 per cent. on the average. After the eighteenth day they rise to 15–20 per cent., and sometimes to 30 per cent. Corresponding to the diminution of the polymorphonuclears there is a well-marked increase of lymphocytes. During the first week they are 45 per cent., in the third week 65 per cent., and later they are still 40–50 per cent. Readings of 60–75 per cent. are not unusual. The large mononuclears are also increased, especially in the first two weeks, being on the average 4–8 per cent., and not infrequently 20 per cent. Specially characteristic of small-pox is the appearance of pathological cells in the blood in the form of myelocytes which are hardly ever absent. In the first three weeks they amount to 1–3 per cent., and often number 4–5 per cent., and even 10–12 per cent. Later they become somewhat less numerous. A similar blood picture is only to be found in varicella, in which, however, the total number of leucocytes is generally rather diminished with an occasional slight rise about the eighth to tenth day of disease (10–12,000). Prof. Hoffmann thinks that in suspected cases examination of the blood may be of diagnostic value. (3) No striking changes were observed in the number of red corpuscles and hæmoglobin content, nor did the red corpuscles show any pronounced degenerative changes.

[1] Münchener medizinische Wochenschrift, August 10th, 1923.

MEDICAL RESEARCH IN JAPAN.

We have lately received a number of publications from Japan which testify to the activity with which medical research on modern lines is pursued in that country. In the first place there are several bulky numbers of the twenty-ninth and thirtieth volumes of the well-known journal *Mitteilungen aus der Medizinischen Fakultät der Kaiserlichen Universität zu Tokyo*, with many solid papers on a great variety of subjects—lymphoma leukæmia and allied conditions, mathematical hydrodynamics of cerebro-spinal fluid, the culture of rabies virus in vitro, and so forth. Next there are three parts of a new journal issued by the National Research Council of Japan as the *Japanese Journal of Medical Sciences: Abstracts*, which gives abstracts (in some cases titles only) in German or English of the papers published in the Japanese periodicals. In some of these the papers appear in a European language, and would be easily available to those who were in the habit of consulting the journals in question. But many of them are originally in Japanese, and this new publication certainly gives a surprising revelation of the bulk and quality of medical research which is printed in a form which makes it quite inaccessible to most people who might be interested. The topics and the way in which they are dealt with are quite Western in character, and it is interesting to compare the number of abstracts appearing under each head with their representation in European and American work. Part I. includes pathology (260 items); Part II. physiology (25), pharmacology (53), biochemistry (144), serology (41), forensic medicine (6), protozoology (3), bacteriology (138), hygiene (36), and anatomy (95); Part III. internal medicine (13), surgery (9), gynæcology and tocology (95), dermatology (321), urology (120), ophthalmology (106), pediatrics (106), oto-rhino-laryngology (77), and psychiatry and neurology (45). Thus pathology in our own wide sense accounts for 442 and clinical subjects for 872; to which it should be added that many of the abstracts in Part III. deal with purely laboratory investigations—e.g., comparisons of the Sachs-Georgi and Wassermann reactions are under dermatology, not serology. From all of which we may surmise that in Japan, as in this country, "medical" research tends to desert the wards for the allied field of the laboratory. The third publication to notice is the first volume of *Scientific Reports from the Government Institute for Infectious Diseases*, of which Prof. M. Nagayo is the director. This contains complete reprints of most of the papers published from the institute during 1922, translated into a "foreign language" under the editorship of Dr. Y. Miyagawa. The non-Japanese language is English in 34 papers, German in nine, and, which will please Prof. F. G. Donnan, in three Esperanto.

A cursory survey of these publications shows that a very large amount of active research work has lately been done in Japan. We can only hope that too much damage to personnel and material has not been done by the disastrous earthquake. Progress in recent years has been vigorous and determined, and the set-back, which must at the best be substantial, is surely a sad disappointment to those who have striven to build up higher education in Japan and bring their results to the notice of workers elsewhere. And it is entirely in a friendly spirit that we would remark that the imitation of Western medical research is so complete that under that name is included a good deal of work which, invaluable as post-graduate education, does not really add to knowledge, and that the free publication of these exercises increases still more the already impossible task of anyone who tries to keep abreast of advances in any but some very small corner. Will the Japanese be the first to take the step which must follow the present incoherence sooner or later, and bring up groups of scholars whose business it will be to forswear the fun of investigation and live laborious days in synthetic analysis of the data which have been already accumulated? It is a great opportunity which lies open to any school; what the world wants is discoveries not researches.

ON THE PATHOGENESIS OF DEFICIENCY DISEASE.

In the current number of the *Indian Journal of Medical Research* Dr. R. McCarrison has published his experimental researches undertaken during the last year upon the relationship between food-metabolism, iodine intake, and thyroidal activity, as well as upon the effect of insanitary conditions upon the thyroid hyperplasia. For this purpose tadpoles and pigeons were employed. Paying very particular attention to the technique of administering fat and iodine to these creatures, he has concluded that excess of fats in the food of tadpoles causes retardation in their rate of growth, and that this can be controlled by the administration of iodine in amounts of 0·5 to 1 mg. of food mixture. The effect induced by linseed oil and cod-liver oil cannot, however, be controlled in this manner. On the other hand, abnormal metamorphoses can be induced by a high iodine intake, and can be hastened by administering at the same time a higher proportion of butter. His former experiments with pigeons have shown that an excess of butter in the diet favours the development of thyroid hyperplasia similar to that in Graves's disease; but more recently he concludes that the confinement of these birds in cages which have become grossly contaminated by excreta is also a potent cause of thyroid enlargement, and that this pathological condition is not due to lack of exercise but to actual contamination of food and water by the birds' own excreta. This can be prevented by scrupulous cleanliness and by the administration of chlorine to the water. It may be that the effects of fat excess upon thyroid hyperplasia are in some way related to bacterial contamination of the digestive tract. It is curious to note that the administration of cod-liver oil affords complete protection against goitre induced by the insanitary conditions already referred to.

X RAY DIAGNOSIS OF PREGNANCY: ITS MEDICO-LEGAL VALUE.

An echo of l'affaire d'Evreux, which created much interest and not a little consternation in France and Belgium some time ago, is to be found in *Paris Médical* for Sept. 8th. It will be remembered that a certain Dr. Vallet was sued by the relatives of a lady, Mme. Jouenne, on whom he had operated on the assumption that she was suffering from a fibroid tumour. This unfortunate operation ended in a Cæsarean section and the death of the patient, whose parents brought an action for malpractice against Dr. Vallet. The action ended in favour of the plaintiffs, and in passing judgment on the surgeon, who had set out to remove a fibroid, and who had found a viable infant in its place, the legal authorities appeared to have been largely influenced by Dr. Vallet's omission to employ the X rays as an aid to diagnosis before operation. The author of the paper in *Paris Médical*, Adrien Peytel, Advocate of the Court of Appeal, points out that the judges seem to have convinced themselves that from the fifth month of pregnancy onwards it is increasingly easy to demonstrate the presence of a fœtus by the X rays. In his defence, Dr. Vallet maintained that the evidence of the X rays in such cases is not always reliable, and that the risk to the mother and infant are not negligible. This defence was not accepted. Was it sound? Mr. Peytel has inquired into this matter, soliciting the opinion of an expert radiologist, whose views are recorded in some detail. It would appear from the opinion of this expert, Dr. Foveau, that if the X rays are to be employed in the diagnosis of pregnancy, specially valuable and fragile apparatus is required, the radiologist must be highly skilled, and even when these conditions are fulfilled, it may not always be possible to give a definite opinion as to the presence or absence of pregnancy. In a case such as the one under discussion it would therefore be natural for the surgeon to hesitate before recommending a diagnostic procedure which is at once costly and uncertain. If an X ray specialist can express doubts of the reliability of a radiographic diagnosis of pregnancy, the ordinary surgeon may surely be excused if he hesitates to apply this costly diagnostic test in every case of abdominal tumour about the nature of which he has doubts. Considering what a number of tests have been devised for the diagnosis of practically every complaint to which flesh is heir, and in view of the unreliability of many of them, it seems unfair that a court of law should lay stress on one particular test of uncertain value. If every known test of a suspected morbid condition had to be carried out before a surgeon operated, he might often find that, at the completion of these tests, the patient had passed beyond the stage at which an operation could be of any use. Judgments such as those of l'affaire d'Evreux serve the sinister purpose of encouraging the surgeon to hold his hand and leave the patient to die of "natural causes."

MONOGRAPHS IN SETS.

THE custom of selling an encyclopædia in sets only has advantages and justifications which are obvious, but we can see none for the course followed by the publishers of the five "Surgical Monographs" reviewed in our present issue. Books on such subjects as the reconstructive surgery of the upper extremity, gastro-enteroptosis, transplantation of tissues, traumatic shock, and the surgery of the spleen are only obtainable together at the price of £6 5*s.* for the set. If a tradesman were to refuse to sell an egg unless his customer bought a sausage, an onion, a can-opener, and a banana as well it would not be long before he had to put the shutters up permanently. This is, of course, the business of the publishers, but we are concerned here with the unfairness to the authors of the admirable monographs and to those purchasers who are interested, for example, in orthopædics but are not in the least concerned with abdominal surgery. We protest strongly against this innovation and trust that British authors will protect themselves from any attempt to tie their works to that of others.

THE PROBLEM OF IDIOSYNCRASIES TO MYDRIATICS.

IN *Le Scalpel* for Sept. 1st Dr. G. Kleefeld, of Brussels, has discussed a subject which is of interest to general practitioners as well as to oculists. It is that of idiosyncrasy to atropine and other mydriatics derived from the vegetable kingdom. Exact information as to the frequency with which such cases of idiosyncrasy occur is lacking, but there is no doubt as to the alarming character of the symptoms of atropine poisoning in these cases. If other mydriatics of the vegetable kingdom could be substituted for atropine, the problem would be comparatively simple, but when the patient shows an idiosyncrasy to all the plant mydriatics, it may be difficult to decide on what to do. Dr. Kleefeld records the case of a man, aged 46, suffering from acute iritis. One drop of atropine was instilled, and on the same day an eczematous swelling of the lower eyelid developed. Treatment with atropine was, however, continued, with the result that the eczema rapidly spread to the upper lip where a bullous eruption appeared. Soon it became infected, an impetiginous appearance being given to it. It was thought that the atropine used might have deteriorated, although it had proved satisfactory in other cases; but no better results were obtained with fresh or sterilised solutions of atropine. An ulcer developed on the cornea, and a hypopyon formed in the anterior chamber. Though a weak solution of scopolamine replaced the atropine, matters became worse. Then an oily suspension of homatropine was substituted for the scopolamine, but with no better results. Cocaine was then tried, again with no benefit, and in the end the instillation of mydriatics was abandoned altogether. Meanwhile the ulceration of the cornea had extended in spite of the application of astringents, and paracentesis had to be performed. An extensive leucoma developed largely because of the failure attending the use of the mydriatics. Some time later the patient was readmitted to hospital with acute iritis of the other eye. The instillation of atropine had the same disastrous effects as on the former occasion. Parenteral injections of milk were given without benefit, and changes were again rung on scopolamine, homatropine, and cocaine, but with no better results than before. Failure changed to success only when plant mydriatics were abandoned in favour of the synthetic euphthalmine, a hydrocyanic derivative of methyl-vinyl-diacetonalcamine. In a 2 or 4 per cent. solution this drug maintains mydriasis for four to five hours, during which there is no paralysis of accommodation. This drug must be used with caution for fear of glaucoma and blepharo-conjunctival catarrh, but, used as a powder and not in solution, Dr. Kleefeld has, during the past two years, found it a very effective mydriatic, and he has not known it to give rise to troublesome sequels. Its suitability in cases of atropine idiosyncrasy adds appreciably to its value.

MENINGITIS DUE TO WORMS.

Prof. P. Gautier and Dr. R. Guder,[1] of the Children's Clinic at Geneva, remark that as long ago as 1863, when Lebon endeavoured to make a distinction between the two conditions, the occurrence of meningitis due to worms in children and adults and its resemblance to tuberculous meningitis had been described. Subsequently numerous cases of meningitis due to worms were published, but were regarded with scepticism by many critics who looked upon them rather as examples of meningism or pseudo-meningitis, owing to the occasionally mild and vague character of the clinical symptoms and the absence of any obvious changes in the meninges caused by the presence of the intestinal parasites. It is only recently that the cerebro-spinal fluid has been studied in detail, as in the cases recorded by Guillain and Gardin, and Lancelin, as well as in one which came under the present writers' observation in a boy aged 5 years. The clinical symptoms in all three cases were identical with those of tuberculous meningitis, but disappeared after expulsion of the intestinal parasite, which in the case of Guillain and Gardin was *Ascaris lumbricoides*, and in those of Lancelin and the present writers *Tænia solium.* Apart from the absence of the tubercle bacillus the changes in the cerebro-spinal fluid—viz., hypertension, lymphocytosis, excess of albumin and cells, and a positive Pandy's reaction—were the same as in tuberculous meningitis. As regards the pathogenesis of the condition which, owing to the changes in the cerebro-spinal fluid is undoubtedly meningitis, the reflex theory no longer holds good, and the only satisfactory explanation is the action of the toxins of the worms on the meninges and nerve centres. The presence of these toxins has been proved experimentally by Simonin, who by injecting extracts of different worms into animals was able to produce nervous symptoms, such as tremors, contractures, and paralyses. In the human subject, as Guillain and Gardin point out, the meningeal symptoms are doubtless produced by the toxins of the parasites reaching the cerebro-spinal fluid by the choroid plexuses or the blood-stream. Several suggestions have been made to explain the rarity of this form of meningitis in spite of the frequency of helminthiasis, such as the condition of the intestinal canal favouring the toxic action of the parasites, the greater toxicity of the worms at certain times, and the increased permeability of the intestinal wall. The chief cause, however, is to be found in the neuropathic character of the individual, as is shown by the fact that in many of the cases there was a history of nervous antecedents such as convulsions or Little's disease. A clinical diagnosis between this condition and tuberculous meningitis will be difficult if not impossible, apart from the therapeutic test. In any cases of doubt, therefore, an anthelmintic treatment should be tried. In cases of tuberculous meningitis it will do no harm, while, if intestinal parasites are responsible for the condition, a rapid and complete cure will be effected.

---

SYPHILIS OF THE ORBIT.

Dr. Jarold E. Kemp,[1] of the Syphilis Department of the Medical Clinic, Johns Hopkins Hospital, who records four personal cases due to acquired syphilis, remarks that syphilis of the orbit, first described by Boerhaave in 1749, is a rare manifestation of the disease, not more than 150 authentic examples having previously been published in either acquired or congenital syphilis. The condition was found in only 5 of about 6000 cases of syphilis at the Johns Hopkins Hospital, and in only 17, or 0·013 per cent., of 130,000 patients with all types of eye disease seen in the Leipzig Clinic prior to 1909 (Birch-Hirschfeld). In most cases the periosteum is first involved, and the bone is secondarily invaded, but in some cases there is a true syphilitic osteitis. The histological appearances are the same as in gummatous processes in the soft tissues, and sometimes cannot be distinguished from tuberculosis. The earliest symptom is pain, which may precede the other symptoms by weeks or months, and is usually nocturnal or constant with nocturnal exacerbations, and is intensified by pressure over the globe and on attempting movements of the affected eye. It often radiates over the side of the head involved, and may be referred to the circumference of the orbit. Exophthalmos is practically constant, but its degree depends upon the situation and duration of the lesion. In the early stage it is absent or slight, but later it becomes very pronounced. As the result of pressure on important structures within the orbit—viz., the optic nerve, blood-vessels, and motor and sensory nerves—a number of other symptoms appear. In the early stage, when pain is the most prominent symptom, there may be little or no disturbance of vision, and ophthalmoscopic examination reveals only slight haziness of the disc and congestion in the vessels. In a later stage loss of vision and changes in the optic nerve, such as unilateral choked disc followed by secondary optic atrophy, set in. Ocular palsies, such as internal, external, or complete ophthalmoplegia, may occur, and are determined by the site of the lesion and the nerves involved. Numbness and tingling of the skin of the forehead and cheeks from pressure on the first and second branches of the trigeminal nerve is a frequent complication, and on examination complete anæsthesia, hypæsthesia, or hyperæsthesia of the skin supplied by these nerves is found. Trophic lesions of the lids and cornea are sometimes present. Pressure on the arteries and veins gives rise to congestion and œdema of the lids, chemosis of the bulb and conjunctiva, and sometimes dilatation of the temporal vessels. The most serious complication of orbital syphilis is rupture of the gummatous process into the neighbouring cavities, such as the cranial cavity, and nasal and paranasal air spaces, giving rise to secondary infection and fatal meningitis. In the absence of treatment the prognosis of orbital syphilis is bad. Not only is complete blindness almost certain to occur from secondary optic atrophy, as in one of Dr. Kemp's cases, but there is always the risk of fatal meningitis. The lesion usually heals more slowly in congenital than in acquired syphilis. Under early and vigorous treatment the results are often brilliant, as in two of Dr. Kemp's cases, in which the pain was relieved and the vision restored to normal by a few doses of arsphenamin.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XLI.—TREATMENT OF RETENTION OF URINE.

RETENTION of urine is caused by a number of widely differing factors, which may be grouped under three headings—mechanical, reflex, and nervous. It may, moreover, be complete, when no urine whatever can be passed and the distension of the bladder gives rise to intense pain (acute retention), or incomplete, where the patient can pass a certain quantity of urine but cannot empty his bladder. The residue left behind varies from a few drachms to several pints; clinically a distinction between cases with over-distension and those without is important, as the treatment should be varied according to the amount of distension present. It is not attempted here to deal with the treatment appropriate to all the different types of retention; I will confine myself to some of the most common of the difficult problems.

Retention Due to Stricture.

Retention following stricture may be due to several causes. (*a*) Impermeable stricture (so tight that no urine can pass through it) is rare, because the patient usually comes for relief long before this stage is reached. (*b*) In cases of moderately tight stricture, retention may follow excess in alcohol, over-indulgence in food, or constipation. (*c*) Even in cases of large calibre stricture retention often follows dilatation, especially if several instruments, or too much force, have been used. (*d*) An acute urethritis often causes retention in patients with stricture, of whatever calibre.

(*a*) In cases where the stricture is so narrow that it causes complete, or almost complete retention, attempts should be made to pass a very small (2 or 3 F.) gum elastic bougie; if it passes easily it may be followed by others, until the size which is gripped by the stricture is reached. The patient will probably then be able to pass urine, and further dilatation should be postponed for a few days. If, however, there is considerable difficulty in passing the finest filiform, it should be tied in place and the patient put to bed. The urine will trickle alongside the bougie, and can be collected in a urinal. On successive days this operation should be repeated, increasing the size of the bougies until the patient is able to pass urine naturally. Subsequently the stricture should be gradually dilated at weekly intervals. If no instrument can be passed at the first attempt, the patient should be put to bed and given an enema, followed by 30 ♏ tr. opii and a hot bath. If no urine is passed in the bath, a second attempt to insert a filiform should be made, and, if necessary, a third, under anæsthesia. If a filiform can be introduced it should be followed by the guide of a urethrotome, and an internal urethrotomy performed. If no instrument can be passed under anæsthesia, a Wheelhouse operation should be performed immediately. Soft gum elastic bougies are the safest instruments for dealing with tight strictures. Fine whalebone or metal bougies are dangerous on account of the ease with which a false passage is made. Occasionally a gum elastic bougie coils up in the urethra without passing the stricture, when the coil can be felt by palpating the perineum. It is useless to attempt catheterisation unless the urethra will admit a No. 6 F. bougie easily.

(*b*) Retention following alcoholic excess is due to congestion. A moderate-sized bougie (6 to 10 F.) usually passes easily, and if the patient cannot then empty his bladder the urine should be drawn off by means of a fine catheter. The patient should be given a brisk purge (calomel, followed by salts) and sent home to bed. In rare cases the catheter must be passed night and morning for a few days, but it is better not to attempt regular dilatation until spontaneous micturition is well established.

(*c*) Retention following instrumentation is also due to congestion, and is usually of short duration. If the patient is in distress, either a bougie or catheter about two sizes smaller than the last instrument used may be inserted, but not till the purge, followed by a hot bath, has failed. Intermittent dilatation should be carried out very slowly by one size at each sitting, since retention follows too rapid dilatation. If it is essential to dilate a stricture rapidly, internal urethrotomy is much safer and more efficacious than forced dilatation.

(*d*) In cases of stricture complicated by acute urethritis retention is caused either by the severity of the urethritis or by the use of too strong injections or irrigations. A catheter should not be used unless all other methods (purges, hot baths, sedatives, &c.) have failed. The urethra should first be washed out with sterile saline or very dilute (1 in 12,000) oxycyanide of mercury solution, when a small soft catheter may be passed; acute retention is the only indication for passing an instrument along an acutely inflamed urethra.

Retention Due to Foreign Bodies Impacted in Urethra.

This is almost invariably due to impacted calculi, as foreign bodies introduced from without tend either to pass into the bladder, or are small enough to be expelled by the flow of urine. A stone may be impacted (*a*) in the posterior urethra, when it should be pushed back into the bladder by means of a full-sized steel sound, and immediately crushed; (*b*) in the bulb if the urethra is strictured, when it is best to cut down on the urethra, remove the stone, and at the same time divide the stricture; or (*c*) in the fossa navicularis, whence it can be removed by means of a fine forceps, after section of the meatus itself.

Prostatic Retention.

In cases of prostatic abscess, which is the most frequent cause of retention occurring in the course of an acute gonorrhœa, spontaneous micturition is always re-established as soon as the pus is evacuated, and the patient should not be catheterised unless it is impossible to operate immediately. The prostate should be exposed in exactly the same manner as in perineal prostatectomy, and both lobes should be incised and drained. It is a mistake to open these abscesses either through the rectum or urethra, as troublesome fistulas result. In cases of acute prostatitis, a catheter should be passed if the retention is complete, or if the bladder can be felt rising above the pubis after micturition. The urethra should be irrigated with a very mild antiseptic beforehand, and the bladder should also be washed out after the urine is evacuated. The utmost gentleness is necessary in treating these cases, as rough instrumentation may result in an abscess.

Prostatic obstruction in elderly men is due to benign or malignant enlargement of the gland. The radical treatment of this type of obstruction is, of course, prostatectomy, and catheterisation should be looked on either as a preliminary to removal of the gland, or as a palliative measure in cases where operation has been refused or is definitely contra-indicated.

(*a*) *Benign Enlargement.*—Three types of retention are met with in these cases: partial retention without distension, partial retention with distension, and complete retention. In the first type, it is better not to pass any instrument until operation has been decided on, especially if the abdomen is resonant down to the pubis, and the bladder cannot be felt after micturition. A rough estimate of the amount of residual urine can be obtained by bi-manual palpation, with a finger in the rectum. When the patient is in hospital a catheter must be passed to carry out renal function tests, and the residual urine should be measured at the same time. The chief exceptions to this rule are: (1) cases where malignancy of the prostate is suspected, when the bladder should be emptied to facilitate examination of the gland; (2) where the symptoms suggest the presence of a new growth of the bladder, &c., in addition to prostatic enlargement, when an early cystoscopy is indicated. In the second type of case, the bladder can be felt as a pear-shaped tumour in the lower abdomen, which often extends as high as the umbilicus. These patients usually have overflow incontinence and badly damaged kidneys, and are always in a critical condition. The sudden emptying of an over-distended bladder is usually followed by severe hæmaturia, which may end in complete suppression of urine. It is therefore necessary to evacuate the contents of the bladder very slowly, and the treatment should not be commenced until the patient has been put to bed. A catheter, armed with a spigot, may then be introduced and tied in place; the spigot is removed every hour, from four to five ounces of urine allowed to escape. If the urine drains away too quickly a corresponding amount of sterile saline should be injected into the bladder. The patient should drink at least five pints of barley-water, or some other diuretic fluid daily. The height of the bladder tumour should not fall by more than an inch a day. Once it is completely emptied (after four to five days) it must on no account be allowed to refill, and either a one- or a two-stage prostatectomy (according to the renal efficiency) should be performed. Many surgeons prefer to do an immediate cystotomy on these patients, and to empty the bladder slowly through the suprapubic tube. Either method is satisfactory if strict care is taken to avoid infection. When complete retention follows a chill, indiscretion of diet, or occurs without obvious cause, the power of spontaneous micturition generally returns in a few days, but occasionally the retention becomes chronic. Acute retention is always exceedingly painful, and demands instant catheterisation; the withdrawal of 15 oz. will completely relieve the patient, who should then be put to bed. If his bladder is distended it should be emptied by slow drainage, described above; if not, it may be completely emptied by a catheter passed three times in the 24 hours.

(*b*) *Retention Due to Malignant Disease of the Prostate.*—The same types of retention occur as in cases of simple enlarged prostate, but the malignant gland does not as a rule give rise to marked obstruction until the tumour is inoperable, so that a permanent cystotomy is usually the only possible operation. It should be performed early, and catheterisation should only be looked on as a preliminary to this operation.

Clot Retention.

This difficult and painful type of retention is caused by any hæmorrhage copious enough to allow of the blood coagulating in the bladder. The hæmorrhage may come from the posterior urethra (false passage), from the prostate (rupture of a small vein on its surface), from the bladder (hæmorrhage from a new growth), or from the kidneys (trauma or new growth). When the source of the hæmorrhage is diagnosed, it is still difficult to decide whether the bleeding is progressing or has ceased. In the former case the hæmorrhage should be checked before emptying the bladder, in the latter the bladder must be emptied first. If the blood is bright-red the bleeding is usually active; if a black tarry mixture of blood and urine is withdrawn it has ceased. The clots should be washed out by means of a large metal catheter, since small instruments quickly become blocked with blood-clot. If this happens, a small quantity of lotion (about one or two ounces) may be forced through the instrument by means of a powerful syringe to clean it. The bladder should be syringed out until the lotion returns clear, which may take an hour. In extreme cases a Bigelow's evacuator may be required. When the bladder is free from clot a soft catheter should be tied in, and the patient encouraged to drink as much as possible. If the hæmorrhage is continuing an immediate operation is necessary. In renal cases there is usually little difficulty in diagnosing the side affected. If the bleeding comes from the bladder itself, or from the urethra, a cystotomy is indicated. The clots should be turned out, and the hæmorrhage controlled either by removal of the cause or else by packing.

J. SWIFT JOLY, F.R.C.S.,
Surgeon, St. Peter's Hospital for Stone, &c.

Special Articles.

THE REMUNERATION OF INSURANCE PRACTITIONERS.

The following letter has been received from the Ministry of Health in reply to the communication from the Insurance Acts Committee of the British Medical Association (see The Lancet, Oct. 13th, p. 849), and it will be seen that the Minister of Health definitely declines to accede to the recommendation of the Committee that the question at issue should go to arbitration.

Sir,—The Minister of Health has given most careful consideration to your letter of the 8th instant indicating the views of the Insurance Acts Committee on the offer to insurance practitioners made in my letter of the 3rd instant.

The Minister does not propose to return a detailed answer to your letter. He does not, of course, accept the statements and arguments in that letter as accurate or sound, but he thinks the main issue will only be obscured by prolonging paper controversy. Lest there be any ambiguity as to the position, he desires me to state quite clearly that the offer made in my letter of the 3rd instant represented a considered decision given by him in a matter in regard to which the responsibility rests on him as a Minister of the Crown. Before arriving at that decision he naturally weighed to the best of his power the claim and the representations made on behalf of the profession and the views of the approved societies. But the decision is his decision, arrived at on the merits of the case. He maintains the view that the alternative offers made represent a settlement fair alike to the profession and to the insured population. He most earnestly hopes that on a fuller consideration the profession may see their way to accept one of the alternatives, knowing, as he does, that they realise the undesirability of prolonged controversy on a matter of this kind.

He would wish me to say something only on two points in your letter, the question of rural practitioners and the question of arbitration.

As regards rural practitioners, he is very sensible of the peculiar difficulties of their position, and is very desirous of finding a remedy. The matter is now receiving his serious consideration, but, as already stated, he does not think that it can or should interfere with a settlement of the general capitation fee, the administrative objection to differential capitation fees being overwhelming.

As regards the question of arbitration, the Minister cannot forget that the basis of remuneration was exhaustively considered by an arbitration tribunal some three years ago, and he has accepted their award as one of the data on which the Government's offer has been determined. Any further arbitration would lead to undignified disputes between the doctors and the approved societies, which are to be deprecated in the interests of successful working of the panel system, and the Minister himself has in fact regarded his position as that of an arbitrator with the added responsibility of his Ministerial duty.

I am, Sir, your obedient Servant,

(Sgd.) W. Arthur Robinson.

Dr. Cox, the Medical Secretary of the British Medical Association, has sent the following reply :—

Sir,—I beg to acknowledge receipt of your letter of the 15th October. The Committee understands :

1. That the Minister is unable to accept the suggestion that arbitration offers a method of arriving at a peaceful arrangement.

2. That he is unwilling to allow any further negotiations until he has been convinced by some other method that it is impossible for him to obtain a satisfactory service under his present offer.

The Committee would have preferred the method either of arbitration or of negotiation, but has no option but to accept the responsibility he now imposes on it.

The Committee's position is (1) that on the purely economic question, on which it is still prepared to negotiate, the remuneration the Minister suggests is insufficient, and that there has so far been no real answer to the facts and conclusions set out in the Committee's first memorandum M 1 and the accompanying statement by Professor Bowley.

(2) That no national medical service based on an insurance system can be satisfactory unless it attracts all types of general practitioners in sufficient numbers and so supplies the industrial population, whether in town or country, with that choice of doctor and satisfactory service which obtains among other classes of the population.

(3) That while willing to serve the community to the best of its ability and to make any satisfactory arrangement to this end with the representatives of the community, the profession is not prepared to accept the position of being under the dominance or control of a particular section.

(4) That arrangements consistent with these principles can be agreed to by the Committee, and would not, in its opinion, involve any further contribution from the taxpayer or any diminution of the benefits to which insured persons are entitled.

I am, Sir, your obedient Servant,

Alfred Cox,
Medical Secretary.

Insurance Practice : Conference at the Ministry of Health.

A Conference, presided over by Sir Arthur Robinson, the First Secretary to the Ministry of Health, accompanied by other officials of the Ministry, took place on Tuesday, Oct. 16th, between representatives of the Consultative Councils of Approved Societies and representatives of the Insurance Acts Committee of the British Medical Association. The Conference met to discuss certain outstanding questions relating to the scope and character of the service to be provided by insurance practitioners. The question of the remuneration of insurance practitioners was not discussed.

Sir Arthur Robinson reported to the Conference that some misunderstanding existed in regard to a statement attributed to Dr. Brackenbury, the chairman of the Insurance Acts Committee, and said to have been made by him at a Conference of Local and Medical Panel Committees held on June 7th, to the effect that the Insurance Acts Committee could not agree to the claim that every practitioner should do for his insured patients all the things which he was accustomed to do for his private patients.

In order to remove any misapprehensions in this matter, Sir Arthur Robinson quoted the exact words used by Dr. Brackenbury, which were as follows :—

> "Everything which was, properly speaking, of a general practitioner kind should be within the service, and everything which was properly of a specialist kind, whether performed by a man who did that thing only, or by a general practitioner who had made himself specially skilled in that thing, should be outside the service. This division had been attempted by the Insurance Acts Committee in the form of two schedules, one showing the services included in the contract, the other the services not included. What a general practitioner did as a general practitioner was inside, what a general practitioner did as a specialist was outside. The claim that every practitioner should do for his insured patients all the things which he was accustomed to do for his private patients was not one to which they could agree for one moment. In so far as a general practitioner was in any degree a specialist, his specialist services were outside the contract, and he should have a right to charge for them."

Labour Proposals.

The General Council of the Trades Union Congress and the Labour Party National Executive have prepared a pamphlet dealing with National Health Insurance Medical Benefit. They recommend as a basis of the panel service :—

Free choice of doctor.

Limitation of panel lists to 2500, or 4000 when an assistant is kept.

Panel doctors not to be permitted to keep more than one assistant except in special circumstances. Partners to be regarded as permanent deputies.

Better surgery accommodation.

Simplification of the certificates which doctors must sign.

Revision of the system of dealing with so-called "excessive prescribing."

More effective means of securing the removal of unsatisfactory doctors from the panel.

An agreement for a period of five years.

If requirements effectively fulfilled, a capitation fee of substantially 9*s.* 6*d.*

Institution of dental benefit and provision of increased diagnostic facilities at earliest possible moment.

Suggestions as to revision of methods of financing National Health Insurance are also included in the pamphlet.

TUBERCULOSIS.

Trudeau Sanatorium.

THE thirty-eighth annual medical report of the Trudeau Sanatorium might well be described as a text-book of tuberculosis, with this difference that while most text-books contain much out-of-date information, this report deals with the latest experiences of some of the most eminent tuberculosis specialists in the U.S.A. In his introduction, Dr. Lawrason Brown refers to some very interesting work carried out by Dr. Petroff and Prof. Zinser at Columbia University on skin hypersensitiveness. They attempted to produce it by the use of tubercle bacilli killed by various degrees of heat, and also by the use of two fractions of the tubercle bacillus obtained by hydrolysis. They discovered two bodies, one a mixture of nucleoproteins which produced hypersensitiveness and a skin reaction, and another body which does not produce hypersensitiveness, although it causes a more pronounced skin reaction than the first body. Many interesting problems have been opened up by these investigations which are still proceeding. Dr. Lawrason Brown's essay on tuberculin as a diagnostic agent is worth reading by the many who have abandoned it on account of the mischief with which it has been credited.

> "For more than 20 years we have used the subcutaneous tuberculin test, and have encountered no untoward results of any moment. When I pause to think to-day of the chances we ran in giving the test to many patients with extensive pulmonary tuberculosis but few physical signs, I am convinced that, given as we give it to-day, the tuberculin test is never harmful. We use it only in patients with doubtful or slight parenchymatous X ray lesions, in whom other sufficient data are lacking. Should the test prove to be negative, we return the patient to his home and work, telling him that if he should ever wish to re-enter the institution, we will take him in at once. So far no such patient has ever applied for readmission."

It is strange, but true, that Trudeau Sanatorium, to which tuberculosis specialists all the world over look for inspiration is, according to the grading of the American Sanatorium Association, only a Class B institution. This system of grading was instituted by the National Tuberculosis Association because unsatisfactory conditions were found to exist in many sanatoriums where buildings, equipment, personnel, and service were inadequate. Trudeau Sanatorium lapses into Class B chiefly on account of the lack of infirmary beds; the sanatorium which admits various grades of patients should, if it wishes to belong to Class A, have from 25 to 50 per cent. of all its beds so-called infirmary beds. This standard reflects the growing tendency to regard rest rather than exercise as of therapeutic importance in tuberculosis, and probably most sanatorium physicians with long experience would agree with Dr. Lawrason Brown in his verdict that "the treatment of patients has slowly but definitely changed in the last 22 years."

The Rigours of the Tuberculosis Campaign in Illinois.

The Public Health Department of Illinois has issued a pamphlet dealing with the regulations, put into force since Jan. 1st, 1923, for the control of tuberculosis. It is customary in England to mention, more or less as an after-thought, the penalties attaching to the contravention of a given law. The Illinois public health authorities introduce their readers to the subject under discussion by informing them that health or other officers, not complying with the regulations, are subject to a fine of $200.00 for each offence, or imprisonment in the county gaol for six months. It would seem to be incumbent on practically every person in Illinois to notify tuberculosis to the health authorities, for Rule 1 runs thus:—

> "Every physician, laboratory director, nurse, or other attendant, superintendent of any hospital, asylum, orphanage, gaol, or similar institution, teacher in any school, proprietor or manager of any business, hotel, lodging or boarding house, parent, guardian, householder or any other person having knowledge of a known or suspected case of tuberculosis, shall immediately report such known or suspected case of tuberculosis in writing or by telephone to the local health authority."

According to Rule 4, no person suffering from active or open tuberculosis shall share a bedroom with any other person unless that person is also tuberculous or a nurse under the direction of a physician. There are several other rules conceived in the same spirit. After having made it abundantly plain that to be convicted of tuberculosis may be tantamount to ostracism and persecution, the health authorities of Illinois are perhaps unduly hopeful in expecting a ready response to their plea for early diagnosis.

Yorkshire Tuberculosis Society: Artificial Pneumothorax Work in Dispensary Practice.

On Sept. 29th, at the Tuberculosis Dispensary, Sheffield, Dr. J. Rennie, the President, in the chair, Dr. C. Rolleston, M.O.H., Rutland, gave a paper on artificial pneumothorax work in dispensary practice, the object of which was to demonstrate that such work could be domiciliary and ambulant. The population concerned was 66,000—half in a county borough (occupation engineering), half agricultural, and scattered over 150,000 acres. Annual deaths from phthisis, 49; notifications, 96. The work was begun seven years ago, in which time pneumothorax had been attempted in 71 patients (30 male, 41 female), whose ages ranged from 14 to 60 years. Nine of the 71 had unilateral disease, 59 bilateral, in 53 of whom the affection of the worse lung was in the third stage. The remaining three had bronchiectasis. Sixty-five of the 71 showed positive sputum. The number in whom pneumothorax was established was 50.

Technique.—Injections of 300 c.cm. for the first operation, and not more than 500 subsequently; larger doses might lead to mediastinal dislocation and pleural effusion. The operation was performed twice a week for the first month and once weekly for the next two or three months, all this at the patient's home. Thereafter, generally at the dispensary, twice a month up to six months, and then every three weeks. 1883 punctures had been performed, with no fatalities. Alteration in the manometer reading from change of posture was noticed; in a contracting pneumothorax one was enabled to introduce more air by changing the patient from the dorsal position to the prone, or vice versa.

Results.—The severe nature of the disease, detailed above, must be considered. Thus of the 21 patients in whom pneumothorax was *not* established, owing to adhesions, 14 were dead, and in only 3 of the remaining 7 could the condition be deemed satisfactory. But of the 50 with an artificial pneumothorax the result was excellent in 11, good in 15, equivocal in 3. Some of those who had died, 21 in number, had been afforded temporary relief, being enabled to return to work, or the sputum becoming negative. Two such showed well-marked bilateral disease on X ray examination. The most frequent cause of death was spread to the other lung, laryngeal and intestinal affection occupying the second place. Many failures must be due to postponement of the operation.

General Observations.—Pleural adhesions were hard to diagnose beforehand. Only 13 patients gained weight, the amount varying from 1 lb. to 54 lb. No effect on pyrexia and quick pulse was recorded in 26 cases. In 11 with a normal temperature the pulse was brought down, though sometimes that took months. In seven instances both temperature and pulse were abated. Thus the effect of pneumothorax on pyrexia and tachycardia varied, and the rapid defervescence so often described was rare. Displacement of the heart was noted in 21 left-sided and 15 right-sided pneumothoraces. Cardiac murmurs occurred six times, two being certainly functional. Displacement was an early event, and might persist for years without inconvenience. Six cases of mediastinal dislocation were diagnosed. In a successful case sounds conducted from the collapsed lung were heard on the healthy side. Subcutaneous emphysema was of prognostic value. Thus of 24 cases that had done well, only 2 showed marked emphysema and 17 had none. But 18 unsatisfactory ones had it. Pleurisy occurred in 21 of the 50 cases, generally early; 18 of the 21 had temporary fever. Pleural effusion was difficult to demonstrate; there might be much splashing, but no yield from exploratory punctures. The after-history of two cases sent to Mr. Romanis for thoracoplasty[1] was given. The lecturer advised the provision of motor-cars for tuberculosis officers in sparsely populated districts, as tending to save dispensary accommodation.

Dr. W. C. Rivers, to show that, as evidenced in recent foreign literature, X ray control was not essential, exhibited a patient who three years ago was given three months to live. Now, a year after leaving off refills, there was well-nigh perfect recovery. This case had never been X rayed. On the other hand, he showed pneumothorax skiagrams taken by highly skilled hands which told nothing. He welcomed the paper as inspiring, and gave four differential signs between pleural and pulmonary oscillations.—Dr. C. Woodcock gave some experiences. He had heard an adhesion rupture, seen the uvula emphysematous, and had a case of embolism. He held the frequently advanced opinion that the symptoms of embolism could arise also from pleural shock. A slow induction was best. He agreed with the lecturer that intestinal disease was a contra-indication; laryngitis was not. He thought oxygen gas and a small needle of use in avoiding pleurisy. Dumarest was right in advising that a pneumothorax, if it had to be relinquished, should be left off gradually. The speaker had used pneumothorax for stopping hæmoptysis.—Dr. Z. Fernandez thought that whatever the future rôle of current bacteriological means of treatment might be, these were not specifics, and could not oust lung compression therapy in appropriate destructive lung disease or in obstinate, severe hæmoptysis. Artificial pneumothorax certainly had its failures. In 1921 70 patients were traced who had been under treatment by present or former colleagues from 1912 onwards; 60 per cent. of the 70 were dead; 60 per cent. were dead, too, of 134 cases treated from 1915 to 1920. Coming to more immediate results, 48 sanatorium cases in 1921 and 1922 showed a death-rate of 30 per cent., the material being progressive Stage II. and III. cases. It had been argued that the treatment had not appreciably bettered the Leeds tuberculosis death-rate over that of other Yorkshire county boroughs. In Leeds the bronchitis death-rate was proportionately smaller, however, than in other areas which had a smaller tuberculosis death-rate. In hæmoptysis pneumothorax treatment was now routine, the patient being transferred to hospital when the bleeding had been controlled. As to re-administration of artificial pneumothorax, two of the speaker's cases in which treatment was commenced in 1917 had recurrence on three different occasions, and no difficulty was met with in finding free pleura again. One out-patient had had over 70 refills in four years. Some cases did not require prolonged treatment. The continental technique, recently witnessed by the speaker, of fixed cylinders and rubber bags, was far behind work in England, though in thoracoplasty and in X ray work the continent was ahead of us.—The President and Dr. Keating recommended trial of artificial pneumothorax in dispensary practice.

Demonstrations of Clean Milk Production.—The British Dairy Farmers' Association, in conjunction with the Ministry of Agriculture and Fisheries, and the National Institute for Research in Dairying at Reading has made arrangements for demonstrations on the production of certified and Grade "A" (tuberculin tested) milk to be given at the Dairy Show to be held at the Agricultural Hall, Islington, London, N., from Oct. 23rd to the 26th.

THE LONDON MEDICAL EXHIBITION.

(Concluded from p. 855.)

In The Lancet of last week we enumerated the exhibits of drugs and foods at the London Medical Exhibition, Central Hall, Westminster, Oct. 1st to 5th. The following is an account of the surgical instruments and appliances, and scientific apparatus demonstrated by many well-known firms, and which are likely to be of interest or service to the medical world. To this we add a description of the various prepared milks and milk-foods shown, some notes on the merits of certain British spas represented at the exhibition, and we mention the chief medical publishers who showed many of their new and forthcoming publications.

It is safe to say that no medical man visited the exhibition without seeing something—in one or more of the many sections—which he carefully noted in his memorandum book as likely to be useful in practice. Recent improvements made in the larger exhibits, such as X ray installations, operating tables, &c., could not fail to stimulate interest even in those whose means excluded purchase, but among the many minor appliances embodying some new principle or modification the practitioner would readily pick out some useful piece of apparatus. The same might equally be said of the drugs and foods section; although the therapeutic action of any particular medicament is not demonstrable in five minutes at an exhibition stall, nevertheless the physician could satisfy himself conveniently as to the physical and æsthetic properties of any preparation.

Surgical Instruments.

Mayer and Phelps, Chiron House, 59–61, New Cavendish-street, London, W., in addition to a wide selection of instruments and apparatus for general and regional surgery, made particularly prominent the Reavell-Moseley electric rotary pump for pressure and suction. This is an ingenious and useful apparatus for many purposes, among them being the removal of blood and secretions from site of operations, saving much time in swabbing, the aspiration of the chest and abdomen, and the evacuation of cysts. This is a very silent running piece of apparatus, and is easily portable.—Down Bros., Ltd., St. Thomas's-street, London, S.E., among their wide range of surgical instruments of new and existing patterns made prominent the Ivan Magill new portable intratracheal apparatus, and drew special attention to a new form of self-locking guillotine.—Surgical Mfg. Co., Ltd., Mortimer-street, London, W., and Regent-street, Glasgow, in addition to their attractive exhibit of surgical instruments, operating tables, and various surgical appliances, drew special attention to their new form of "Barton" sphygmomanometer. They also make an instrument for consulting-room use, which is attractively fitted in an oak cabinet.—At the stall of Charles Hearson and Co., Ltd., 14, Princes-street, Hanover-square, London, W., were to be seen a large assortment of bacteriological, pathological, physiological, and botanical apparatus, as well as refrigerating plant suitable for laboratories. Two notable features were the bath for the preparation of "defatted" antigens of bacteria—diaplytes, to use the term suggested by Prof. G. Dreyer (vide The Lancet July 7th, p. 40), and an apparatus for crushing bacteria. The latter, the Thomson bacteria crusher, is made of stainless steel, so that disinfection of the apparatus may easily be carried out, and the knife revolves at from 1000 to 10,000 revolutions per minute. The cuts are made at the rate of 25,920,000 per minute. The bacteria suspended in solution to about 5 c.cm. in volume are totally crushed within 20 minutes and tests which have been made immediately on suitable media have proved negative after the usual period of incubation.—Fassett and Johnson, Ltd., 86, Clerkenwell-road, London, E.C., showed a wide selection of surgical plasters, medicated plasters, surgical dressings, gauzes, and ligatures, as well as dental requisites.—F. G. Ernst, 80–82, Charlotte-street, London, W., showed orthopædic appliances in great variety and made a special feature of ambulatory splints for use in cases of fracture and rheumatoid osteo-arthritis, and Lewis and Sons, 2, Westmoreland-street, New Cavendish-street, London, W., orthopædic appliances of many kinds and surgical instruments in variety. Particularly notable was their improved pattern of Thomas' calliper splint, which is moulded to conform with the tuberosity of the ischium.—Aurorascope Co., Ltd., 18–19, Fulwood House, Fulwood-place, London, W.C., exhibited an ingenious apparatus by which perfect illumination of the ear, throat, nose, mouth, and teeth can be obtained. The instrument can be used for transillumination of the antrum and in retinoscopy and is very portable.—T. Holland and Sons, 46, South Audley-street, London, W., exhibited a large assortment of foot supports, one of the newest being comprised of leather and sponge rubber, and boots for deformities, flat foot, and so forth, were also shown; Scholl Mfg. Co., 1–4, Giltspur-street, London, E.C., a great variety of arch supports and appliances for defects of the feet; and Babers, 309, Oxford-street, London, W. (and at Jersey), boots and shoes of various kinds for correcting deformities of the foot. An interesting novelty among plantar arch supports was shown by the John D. Miller's "Pneumatic" Foot Comforts, 71, New Bond-street, London, W. 1. The invention consists of an air cushion attached to a thin leather sole, and is soft, pliable and extremely light in weight. It has the very great advantage of being easily adjusted by the wearer by means of a clever little valve and pump (supplied to each purchaser of the supports), so as to retain throughout the period of the progressive correction of the arch of the foot, just that amount of support required. Another excellent point about it is that being so pliable, it readily adapts itself to every movement of the foot in walking.—H. E. Curtis and Son, Ltd., 8, Old Cavendish-street, W., had an attractive display of "Curtis" belts, supports and trusses, and elastic stockings, particularly noticeable being the colostomy support which is an adaptation of their original abdominal support for use in cases of active colostomies, affording a general abdominal uplift, a rigid and non-leaking joint at the seat of the opening, and an adjustment that provides ready access to, and removal of, the cup and its contents. The trusses, for all forms of abdominal hernia, proved to be particularly light in weight. A feature of this stall was Colonol, a medicinal liquid paraffin of Russian origin.—Domen Belts Co., Ltd., 456, Strand, London, W.C., showed belts for use in pregnancy, accouchement, umbilical hernia, floating kidney, and gastroptosis, as well as bandages, corsets, and back supports. The belts of this firm are based on physiological principles and received much attention from visitors.—A. G. Sheldon and Co., 59, Weymouth-street, London, W., called attention to a useful exhibit of sterilised surgical dressings and accouchement outfits in sealed packages, which may be obtained according to surgical requirements at any hour of the day or night. They also showed a breast binder and an antenatal binder which possess merit.

Kodak, Ltd., Kingsway, London, W.C., had a remarkable display of reduced negative and positive transparencies on Eastman Commercial and Process Film, and by comparison the value of the increased speed of the new Super-speed Dupli-Tized Films was easily demonstrated.—Messrs. C. Baker, 244, High Holborn, London, W.C., had a display of microscopes, and Ogilvy and Co., 18, Bloomsbury-square, London, W.C., showed microscopes of different kinds, blood-counting apparatus, optical lanterns, and optical appliances for research workers, and especially drew attention to a new electric microscope illuminating apparatus, the feature being an opalite electric bulb with iris diaphragm to suit any voltage.—Sterling Corporation (Great Britain), Ltd., 16, Wigmore-street, London, W., displayed a very efficient and portable high-frequency generator. Made in two styles, with a large selection of applicators, these outfits are ideal for the consulting-room.

X Rays, Ltd., 11, Torrington-place, Gower-street, London, W.C., among their many machines for the application of electricity to the treatment of disease and for diagnostic use, showed a new form of apparatus for treatment by high-tension electrical currents.—De Vilbiss Co., Ltd., West Drayton, Middlesex, nose and throat sprays and an electrical heater for keeping solutions warm in the consulting-room.—Tintometer, Ltd., Colour Laboratories, Salisbury, showed Lovibond's colour scale and Tintometer apparatus for registering the colours of substances, Dr. Dudley Corbett's Radiometer, and the improved form of Oliver's Hæmoglobinometer.—De Trey and Co., 23, Swallow-street, Piccadilly, London, W., exhibited their sterilisers and stainless hypodermic needles.—John Dowell and Sons, Ltd., Globe Works, Chatsworth-road, Clapton-park, E., showed an ingenious infant feeder of the "dummy" shape but designed to administer honey, dill-water, &c., in small quantities.

"Acousticon," Acousticon House, Hanover-street, London, W., showed electrical and non-electrical aids for the deaf; "Acoustique," 95, Wigmore-street, London, W., several kinds of aid for the deaf which have proved useful in suitable cases, and the Acoustique stethoscope, specially designed for doctors suffering from deafness. In this connexion may be mentioned an exhibit of the Marconi Wireless Telegraph Co., Marconi House, Strand, London, W.C., the Otophone, an instrument introducing the principle of the Marconi wireless receivers and intended for aiding the deaf in listening to lectures and concerts. It is also useful in suitable cases for medical men and business men, who are deaf, while seeing their patients and clients. An attachment called the Ossiphone conducts the sound through the bony structures, where such assistance in deafness is indicated.—Deaf Appliance Co., Ltd., 58–60, Wigmore-street, London, W., and Paris, demonstrated the use of many appliances for the deaf, both electrical and non-electrical, and W. H. Pettifor, 11, Victoria-street, London, S.W., showed some interesting electrical aids for the deaf.—Hawksley and Sons, 83, Wigmore-street, London, W., had an attractive exhibit of scientific physiological and acoustic instruments.

Gas Light and Coke Co., Horseferry-road, Westminster, S.W., demonstrated the many uses of gas as an illuminating and heating agent.—Hoskins, Sewell, Ltd., Birmingham and London, exhibited hospital beds, bedding, and equipment for sanatorium, maternity, and children's hospitals, and J. Nesbit Evans and Co., Wednesbury, Staffs, hospital and institution beds.

Milk and Milk Foods.

Ambrosia, Ltd., Brighton Chambers, Denman-street, London Bridge, S.E., with their pure Devonshire dried milk products for invalids, nursing mothers, infants, and convalescents, showed specimens of their cocoa and milk, milk chocolate, and milk rusks.—Glaxo, 56, Osnaburgh-street, London, N.W., exhibited Glaxo Standardised Full-cream Dried Milk containing added lactose and approximating closely the composition of average human milk. Glaxo Three-quarter and Half-cream Dried Milks are prepared to assist the medical man in cases where a lower fat percentage is indicated in cases of fat intolerance or for young and delicate children. They also showed a very interesting exhibit of plate cultivations of Glaxo, spray process dried milk, ordinary roller process dried milk, and cow's milk, illustrating the differences in bacterial purity. A series of transparencies showed cause and result of destruction of antiscorbutic vitamin in spray process dried milk, and absence of this in roller process dried milk.—Thew, Hooker, and Gilbey, Ltd., Buckingham, showed their Hooker's malted milk which contains neither starch nor cane sugar; it has previously been favourably reported upon by THE LANCET.—Horlick's Malted Milk Co., Slough, Bucks, had an attractive exhibit of their easily digested and nutritious diet for invalids and convalescents as well as for infants. It can be obtained in the form of tablets.—Prideaux's Pure Casein and Life Food Co., Ltd., 16, Southwark-street, London, S.E., showed milk foods, whey, and milk powders.—West Surrey Central Dairy Co., Ltd., Guildford, Surrey, gave demonstrations of the utility of Cow and Gate Milk Food, in which only the finest Grade A milk is used.—Trufood, Ltd., The Creameries, Wrenbury, Cheshire, and Lever House, Blackfriars, London, E.C., exhibited pure milk products including humanised Trufood, which closely approximates to breast milk for infants from birth to 4 months, Trufood for infants of 4 months and onwards, and Secway, a sweet whey powder.—Food Products, Ltd., 41, Queen Victoria-street, London, E.C., Bovo-Lactin, consisting of animal protein hæmoglobin, milk solids, and carbohydrates, was shown at this stall in the forms of Invalid Bovo-Lactin, Bovo-Lactin Essence, and Bovo-Lactin chocolate and gruel.—Mead Johnson and Co., 40–42, Lexington-street, London, W., displayed their dextri-maltose and other infant diet substances with instructive booklets for its use. The preparations are intended for prescription by medical men only and no feeding directions accompany the trade packages.—Food Education Society, 329, Vauxhall Bridge-road, S.W., showed a large selection of publications in connexion with food, cookery, and health reform.—Cadbury Bros., Bournville, Birmingham, displayed cocoa and chocolate, and Keen, Robinson and Co., Ltd. (incorporated with J. and J. Colman, Ltd., London and Norwich), preparations of mustard and prepared oats.

Spas.

The attractive and instructive exhibit of the British Spa Federation emphasised the fact that within the limits of climate and altitude British watering-places can successfully compete with foreign resorts, while at the same time possessing many distinct advantages. Bath, Harrogate, and Droitwich were included in this section, and the many photographs, booklets, and analytical tables testified to the enterprise of the organisers. The same remarks apply to Torquay, where special treatments are the seaweed baths indicated in muscular and articular rheumatism, and the Dartmoor peat baths and packs. Firms exhibiting natural and other mineral waters included Apollinaris Co., Ltd., 4, Stratford-place, London, W.; Hydrox, Ltd., Trafalgar House, 11, Waterloo-place, London, S.W.; and Ingram and Royle, Ltd., Belvedere-road, London, S.E.

Publishers.

Medical books were shown by Baillière, Tindall and Cox, Henrietta-street, Covent Garden, London, W.C.; William Heinemann (Medical Books), Ltd., 20, Bedford-street, London, W.C.; H. K. Lewis and Co., 140, Gower-street, London, W.C.; and by Stanley Phillips, 48, Brondesbury-road, London, N.W. Messrs. Minty, of Oxford and London, showed a selection of their book-cases.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

National Health Insurance Commission and Medical Certification.

THE National Health Insurance Commissioners have recently issued a circular letter to medical certifiers, in which it is stated that serious complaints have been received from Approved Societies as to the lax manner in which medical certification is being carried out by some certifiers; as the result of inquiries they are satisfied that these complaints are well grounded. This question was discussed at a recent meeting of the Advisory Committee appointed by the Commission under Section 58 of the National Insurance Act, 1911, and it has been decided to set up a Central Complaints Committee, composed of representatives of the medical profession and of approved societies, with a chairman appointed by the Commission from the members of the Advisory Committee. A summary of the facts against any certifier may be placed before the Central Complaints Committee for their observations before any further steps are taken. The types of complaints the Commission contemplate bringing before the Central Complaints Committee will include cases where a certifier: (i.) issues a certificate of incapacity for work in respect of an insured person without a corresponding medical examination; (ii.) improperly issues a certificate of incapacity for work to an insured person who is not in fact incapacitated; (iii.) issues on the same day in respect of a particular insured person a number of certificates of incapacity for work purporting to have been signed at weekly intervals. Every opportunity will be afforded to the certifier to meet the charge preferred against him. In cases where the Commission are not satisfied it will be open to them: (*a*) to refer the matter to the General Medical Council on a charge of infamous conduct in a professional respect, in accordance with the resolution of the Council dated November, 1911; or (*b*) to terminate forthwith his agreement with them as a certifier; or (*c*) to impose a monetary penalty upon him.

The Commission further draw attention to certain minor changes in the ordinary certificate, and state that they have authorised the issue of a special form of certificate for use in certain cases of prolonged illness.

Royal Academy of Medicine in Ireland.

The annual meeting of the Royal Academy of Medicine in Ireland was held on Oct. 12th, in the Royal College of Surgeons, Dublin, Sir Arthur Chance, President, being in the chair. The annual report stated that the Academy consisted of 173 Fellows, 7 Members, and 36 Student Associates, showing a decrease of four Fellows and one Member, and an increase of 16 Student Associates. Twenty-six sectional meetings were held during the session, with a gross attendance of 949, as compared with 887 in the previous session. Two successful joint meetings of the Sections of Medicine and Surgery were held. During the year Dr. Ernest Hastings Tweedy was admitted publicly to the honorary fellowship of the Academy, and Dr. Oskar Frankl, of Vienna, was admitted *in absentia*. On the same occasion an oration in honour of Louis Pasteur was delivered by Dr. W. R. Fearon. The report recorded with regret the death during the year of two Fellows—Dr. J. M. Finny and Dr. E. C. Hort.

At the election of officers the following were declared elected or re-elected:—President: Sir Arthur Chance. General Secretary and Treasurer: Dr. T. P. C. Kirkpatrick. Secretary for Foreign Correspondence: Dr. L. Cassidy. Presidents of Sections: Medicine, Dr. T. G. Moorhead; Surgery, Sir W. I. de C. Wheeler; Obstetrics, Dr. L. Cassidy; Pathology, Dr. J. T. Wigham; Anatomy and Physiology, Mr. A. A. McConnell; State Medicine, Dr. N. McI. Falkiner.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following table gives some of the principal health statistics for 1922 of four towns, the annual reports of which are commented on below:—

Name of town.	Estimated population (R.G.).	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Respiratory with influenza.	Infant mortality		Maternal mort. from childbirth.
							Legit.	Illegit.	
Glasgow	1,037,800	27·3	17·2	1·5	1·2	4·4	116	181	7·0
Bradford	291,300	17·9	14·0	1·0	1·4	3·0	83	157	5·7
South Shields ..	122,400	26·6	13·8	1·7	1·0	3·5	92	145	5·5
Paisley	85,350	24·8	16·1	1·3	1·3	4·2	117*		4·7

* Undivided infant mortality rate.

Glasgow.

Dr. A. K. Chalmers reports an increase in comparison with the previous year of 2 in the death-rate and of 15 in the infant mortality rate, both largely due to the increased prevalence of influenza, measles, and diseases of the respiratory system. His tables show that both these rates were markedly higher in the four Scottish towns, Glasgow, Edinburgh, Dundee, and Aberdeen than in the four English towns, London, Liverpool, Manchester, and Birmingham. The average rate of the Scottish group for infant mortality was 113, compared with 88 for the English group. Dr. Chalmers compares the infant mortality rates in Scotland and England since 1860, and shows that during the nineteenth century the Scottish rate was much lower than the English, but that both rates showed no tendency to improve; and that in the twentieth century the English rate has improved much more rapidly than the Scottish, with the result that during the decade 1911–20 the English rate is for the first time lower than the Scottish. He suggests that there has been a greater reduction in England under the heading diarrhœal diseases. Table XXIII. shows the infant mortality rate in Glasgow from 1860 till 1922; it has behaved somewhat differently from both the English and Scottish rates. Thus during the last six decades, from 1863 to 1922, the infant mortality rate in Glasgow was 168, 152, 146, 147, 133, and 120. A chart is given, based on the weighings of a number of infants during each week of the first year of life, which indicates that the infants regularly attending the infant consultations are approximately 1 lb. below the standard curve throughout the year. There was difficulty in obtaining satisfactory charts for subsequent years but, so far as they went, such charts indicated that the average child brought to the centres was 2½ to 4 lb. below the standard for the second, 3 to 6 lb. below for the third, and 5 lb. below for the fourth year of life. During April the scheme for supplying meals to expectant and nursing mothers and children under 5 was discontinued gradually. The meals ceased altogether on June 10th, and milk only was supplied on the certificate of a medical officer for necessitous cases in regular attendance at a centre. At the end of the year, as the result of the reports of medical and nursing staffs, the supply of meals was resumed on the conditions governing the supply of milk. Dr. Chalmers gives particulars of the food value of the dinners supplied, in the hope that a standard may be reached for the organisation of adequate feeding in times of trade depression. A satisfactory feature of the V.D. scheme is the increase in the attendances per case. Dr. Chalmers remarks on the great preponderance of females among the cases of congenital syphilis. He also states that "each year the Women's Hospital and Baird-street Reception House treat many cases of very young female children suffering from gonorrhœa, the result of criminal assault," and refers to the appalling belief which exists that gonorrhœa may be cured in this way. It is obvious that the penalty provided by the law for this offence is utterly inadequate.

The portion of the report devoted to housing includes a special joint report by the town clerk and medical officer of health, which shows that the corporation have not sufficient control over sites which have been cleared in over-built areas. Plans are given, showing "hollow squares" in which houses used as dwellings have been condemned owing to congestion, and the position has been aggravated by the conversion of the shell of the dwelling-house into business premises of a greater height than the original dwelling-houses and encroaching still more by backward extension on the already scanty open space of the hollow square. Among the examples given of these new buildings which "obstruct" the remaining dwelling-houses in the square more than the original dwelling-houses did, are a six-story warehouse, picture palaces, and a corporation electricity department building.

The Glasgow Corporation are taking prompt steps to secure their share of the grant of £30,000 per annum offered by the Scottish Board of Health in August, 1922, towards the improvement of insanitary areas, and Dr. Chalmers gives particulars of two schemes which will involve the demolition of over 2000 houses and the erection of a similar number in their stead. The consideration of a memorandum on the Glasgow Common Lodging-houses for Women has led the corporation to adopt a new by-law that no girl under the age of 18 shall be admitted to a common lodging-house unless she is to reside there with her mother. Steps are being taken in various ways towards smoke abatement, by the prosecution of owners and drivers of steam wagons, by the use of coke instead of coal for tar-melting, by central heating and the use of up-to-date appliances. Classes are held for the instruction of firemen and others. A chart is given in the report, showing a pictorial representation of the average soot deposit on each square foot of the city area during 1917 and 1922 respectively. The total year's deposit in the city area was 11,608 tons for 1917 and 7224 tons for 1922, but whether the improvement is due to better methods or not can only be determined when more normal industrial conditions return.

Bradford.

The Bradford report makes good reading because it shows that every problem of public health and school administration is being attacked with energy and thoroughness. There are still some sanitary arrears to be caught up, for there are 7609 privies, but 1501 of these were converted to water closets in 1922. There were 22 smoke prosecutions, only one of which was dismissed. Dr. John J. Buchan reports that most of the steam raised is used for process work and there is great fluctuation in the steam requirements in the dyeing and wool-combing industries, so that, the draught arrangements being frequently designed to meet average loads, there is often deficiency of draught and consequent smoke at periods of maximum firing. Experience has shown, too, that there is often as much smoke with modern as with old-fashioned plants, owing to working with too thick fires and mechanically restricted draught, in efforts to obtain greater evaporation and furnace efficiency. There is a tendency also to adopt intermittent heavy firing, by which means the stoker alternates longer periods of hard work and rest. The tuberculosis rate was the lowest ever recorded, and Dr. Buchan shows that the English and Bradford curves during the last ten years have been similar except that the Bradford rise was higher during the war years. A special report made in April, 1923, on "Tuberculosis in insured persons accepted for treatment by the city of Bradford Health Committee" is quoted to show that, provided the disease is diagnosed in the early stages, the outlook for the patients is quite hopeful even when they return to work in the industrial town in which they contracted the disease. Dr. Buchan shows that the Bradford death-rate from cancer has exceeded the English rate during the last ten years, and that the excess has chiefly been in cancer of the upper part of the alimentary tract (excluding the mouth) in males and females, and in cancer of the uterus.

The infant mortality rate showed a remarkable fall in 1922, while the neo-natal rate has displayed a distinct tendency to fall in recent years. A table is given which shows that the fall in infant mortality since 1896 has been quite pronounced even when diarrhœal diseases have been excluded. Thus the average annual infant mortality rate, excluding diarrhœal diseases, for 1913–22 was 104, for 1903–12 was 115, and for 1896–1902 was 142. Midwives attended two-thirds of the births in 1922 and of these births nearly half were attended by the 11 municipal midwives. When an expectant mother is attended by a non-municipal midwife, ante-natal visits are paid by the health visitors and 504 expectant mothers were so visited in 1922. The municipal midwives paid ante-natal visits to the 1614 cases attended by them, so that rather more than 40 per cent. of all the expectant mothers were under ante-natal supervision by these two methods. The available accommodation for maternity cases in Bradford is 20 beds at the Municipal Maternity Hospital, 40 beds at the Municipal General Hospital, and about 6 at St. Monica's Home which is run by a voluntary agency. Many very serious cases of overcrowding came to light during the year but little could be done owing to house shortage. On June 30th, 1923, the applicants for new houses numbered 7046, of whom 4721 were ex-Service men and of these 3434 lived in apartments. The new houses erected during 1922 numbered 466, including 428 municipal houses. The number of back-to-back houses in Bradford is 40,553, of which 31,792 are built in blocks of four and eight.

The school report shows that 171 cases of ringworm of the head received X ray treatment and that the average period between treatment and re-admission to school was 21 days. As in former years there was no case of recurrence or where there was not full re-growth of hair after treatment. The school dentist, Mr. B. North, reports that 27,127 children, including 1256 in the secondary schools, were inspected and 75 per cent. required some treatment, a gratifying reduction as compared with former years. Mr. North has had much experience of the teeth of children in an area supplied with hard water and is of opinion that the soft water of Bradford is not bad for the teeth. Appointments with the dentist have been well kept, except on Saturdays, indicating the influence of the teachers in this direction. Most of the spectacles needed are provided by the Education Committee. During 1922, 1099 spectacles were supplied. In 966 cases the parents paid the full cost, in 56 cases the cost was remitted after inquiry into the family circumstances, and the remaining 77 pairs of spectacles formed part of the treatment provided at the myope school. The camp schools were not reopened during the summer of 1922. The open-air school at Buckwood, which was opened in 1908, has been extended twice and now has accommodation for 190. Three meals a day are provided and the children are taken to and from school by special tram-cars. The site covers 5 acres and there is free access to about 5 acres of woodland in addition. The usual tables show that every effort is made to provide such education as is possible for all the "exceptional" children in the Bradford area.

South Shields.

Speaking of the high death-rate from tuberculosis, Dr. W. Campbell Lyons says: "So long as the appalling overcrowding due to the lamentable shortage of houses continues, so long will there be a high incidence of tuberculosis." Influenza and pneumonia were prevalent in the early months of the year, and Dr. Lyons thinks the high incidence of acute pulmonary diseases was increased by overcrowding of the houses and lowered resistance owing to unemployment and consequent malnutrition. The number of beds at the Cleadon Park Sanatorium, which was opened in 1921, has been increased to 29. Owing to wretched home conditions and the want of other accommodation for advanced cases, beds have had to be given up to cases for whom no permanent benefit could be expected, to the detriment of cases in a more hopeful stage. The average length of stay in the sanatorium was 115 days. Dr. Lyons points out that the increase in maternal mortality from childbirth is not surprising considering the home conditions, and that a maternity hospital is imperatively needed in the borough.

In the school report the inadequate accommodation at the school clinic is again referred to. Premises were purchased for an open-air school in 1920 but have not yet been adapted for the purpose owing to the economic situation. At the end of the year it was decided to convert 1000 privies into water closets, partly for the relief of unemployment, and Dr. Lyons hopes that once the good work is begun it will go on till all the evils connected with the present system are dealt with and the back streets cease to be breeding places of disease. At the end of the year 353 houses were occupied on the council's housing estate at Cleadon Park and 241 were under construction. During 1922 private enterprise contributed 14 self-contained houses and four houses of flats.

Paisley.

Dr. G. V. T. McMichael reports, as the outstanding event of the year, the generous offer of Miss Russell, of Muirfield, Paisley, to erect and equip a central medical institute for the mothers and children of the town. Two other features of the year's work were the opening in October of the municipal venereal diseases clinic and the decision of the local authority, with the approval of the Scottish Board of Health, to make all forms of pneumonia compulsorily notifiable. In view of present housing conditions, Dr. McMichael is a keen advocate for hospital treatment of pneumonia, and he hopes that the extension of notification will allow more effective treatment to be provided for those fatal types of pneumonia which complicate measles and whooping-cough. Both the general death-rate and the infant mortality rate are the highest recorded for several years, and Dr. McMichael points out that this is due to the increased prevalence of influenza, measles, whooping-cough, and diseases of the respiratory system. No case of pneumonia was refused hospital treatment last year. In commenting on the difference between the death-rates of the larger Scottish burghs and the county districts for 1922—viz., 16·3 and 12·9 respectively, Dr. McMichael expresses the opinion that smoke pollution and the present deplorable housing conditions are the only factors which can explain the difference. In this connexion the following table, given in the report and showing the percentage of the population of the six largest Scottish towns living in houses of from one to three rooms, speaks for itself:—

Town.	One room.	Two rooms.	Three rooms.
Glasgow	12·8	49·8	20·0
Edinburgh	4·7	32·9	22·5
Dundee	8·9	50·8	20·9
Aberdeen	4·4	32·6	31·5
Paisley	12·3	52·3	20·2
Greenock	10·3	48·0	21·1

In another part of the report we read that of the 2118 births, 560 took place in one-roomed houses. Dr. McMichael regrets the decision of the Board of Health to discontinue the 50 per cent. Exchequer grant towards the treatment of measles and whooping-cough in children under 5 years of age, as he considers that expenditure in building up children after such illnesses is far more profitable than the provision of the costlier sanatorium treatment for tuberculosis, which he describes as often futile. Reference is made to the high maternal mortality from childbirth in Scotland—viz., 6·4 in 1921 and 6·6 in 1922, and the high proportion of 96 still-births to 2118 live births in Paisley in 1922. With regard to the latter a careful investigation was made and it was found that the probable cause of 22 of the 96 still-births was "contracted pelvis, followed by instrumental delivery." Dr. McMichael looks to the development of ante-natal treatment as the remedy for this high puerperal mortality and morbidity, for the investigation of which the Scottish Board of Health have recently appointed a departmental committee.

The question of the purification of the River Cart, postponed because of the war, has been taken up again and a small experimental plant is to be laid down for testing the efficacy of the "bio-aeration" method for dealing with the Paisley sewage.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Rear-Admiral Joseph Chambers, the new Director-General of the Medical Department of the Royal Navy, is promoted to Surg. Vice-Admiral.

Surg. Comdr. J. C. G. Reed is placed on Ret. List with rank of Surg. Capt.

ROYAL ARMY MEDICAL CORPS.

Maj. T. J. Wright retires on ret. pay and is granted the rank of Lt.-Col.

Temp. Maj. W. E. Home relinquishes his commn. and retains the rank of Maj.

The undermentioned Capts. retire, receiving a gratuity: W. J. A. Laird (granted the rank of Maj.) and G. H. Wood.

Temp. Capt. J. S. Wilson relinquishes his commn. and retains the rank of Capt.

ARMY RESERVE OF OFFICERS.

Lt.-Col. E. C. Hayes, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

Capt. H. E. S. Stiven, late temp. Capt. R.A.M.C., to be Capt.

ARMY DENTAL CORPS.

Capt. H. J. Pegler, late Spec. List, to be Capt.

TERRITORIAL ARMY.

Majs. A. G. Lovett-Campbell and H. L. Gregory, having attained the age limit, are retd. and retain the rank of Maj., with permission to wear the prescribed uniform.

General Hospitals: Lt.-Col. G. S. A. Ranking, having attained the age limit, is retd. and retains the rank of Lt.-Col. Capt. W. J. S. Bythell (late R.A.M.C., T.F.) to be Capt.

Supernumerary for service with O.T.C.: Lt. E. J. T. Thompson resigns his commn. and retains the rank of Lt.

TERRITORIAL DECORATIONS.

The King has conferred the Territorial Decoration upon Col. P. B. Giles (ret.), Lt.-Col. F. Darlow, and Majs. H. Henry and J. E. N. Ryan.

ROYAL AIR FORCE.

J. S. Wilson is granted a short service commission as a Flight Lt.

INDIAN MEDICAL SERVICE.

Major T. F. Owens to be Lt.-Col.

UNITED STATES PUBLIC HEALTH SERVICE.—The third general interchange of health officers arranged by the health section of the League of Nations is now taking place in the United States. Representatives from France, England, Italy, Russia, Poland, Spain, Holland, Belgium, Greece, Jugo-Slavia, Germany, Switzerland, Norway, Mexico, San Salvador, Brazil, Chile, and Canada, delegated by their respective governments to participate in a course of study and observation, arrived in America the first week in September and will remain for approximately three months. Until Sept. 22nd the delegates remained in Washington, studying national health organisation as administered by the United States Public Health Service. The delegation then separated into three groups, one going to Virginia, another to North Carolina, and a third to Alabama, to study State and local health departments. Later the groups will study health administration in Boston, New York, and Philadelphia, and will probably reassemble in Washington late in November for a final conference.

CENTENARY OF THE LANCET:

CONGRATULATORY MESSAGES.

To the Editor of THE LANCET.

SIR,—I have spent most of my spare time this week in reading, with unwearied interest, the fascinating story of THE LANCET and its hundred years. As a past editor of the *Dublin Journal of Medical Science* for 47 years, may I claim the privilege of associating myself with the many members of the medical profession who have offered you their congratulations in connexion with the Centenary of the famous journal, which has done so much to mould medical opinion, and to advance both curative and preventive medicine throughout the world. For that journal and for you, its Editor, I wish prosperity and ever-growing influence *ad multos annos!*

I am, Sir, yours faithfully,

JOHN W. MOORE, M.D.,
Senior Physician, Meath Hospital and
Co. Dublin Infirmary.

To the Editor of THE LANCET.

SIR,—You have received so many congratulatory letters on the completion of the Centenary of THE LANCET from distinguished members of the profession that a belated one from myself can hardly be expected to add to your gratification.

THE LANCET has had a truly wonderful record, and, apart altogether from the splendid work it has done in disseminating medical knowledge throughout the profession, its pages furnish the best record which we possess of the history of British medicine during the last hundred years. May I congratulate you upon the Centenary Number? What a treasure it will be to all lovers of medical history! Personally I shall regard it as one of the most interesting books in my library. I used to possess one volume which I valued above all others, and that was the first volume of THE LANCET. Like myself, my father and my grandfather, who were both country practitioners, took THE LANCET regularly, and I inherited the first ten volumes from the latter. But, alas! I lent the *first* volume to a friend—I don't remember who—some ten or more years ago; unfortunately he omitted to return it, and I have no doubt by this time he has orgotten who lent it to him. On the fly-leaf is a crest representing a wolf's head with the initials T. S. underneath.

With best wishes for THE LANCET's continued usefulness and prosperity,

I am, Sir, yours faithfully,

HAROLD J. STILES,
Regius Professor of Clinical Surgery,
University of Edinburgh.

DOUBLE SCHOOL VACCINATION.

To the Editor of THE LANCET.

SIR,—In your leading article last week you note he rise in number of cases of small-pox from 7 in 917 to 1225 in the first half of 1923, and discuss the best means of preventing and controlling this disease. The prevalence of small-pox during the last three years has drawn public attention to the chaotic ondition of our vaccination laws, and to the large perentage of unvaccinated people. The number of cases of small-pox has been increasing in every year, save one, since 1917. Cases have been notified for the first time actually in no less than 12 counties since June 1st. The majority of this year's cases have occurred in he epidemic at Gloucester. It has been stated that these cases are mild ones, and even that they are not genuine small-pox. Anyone who saw the photograph in THE LANCET (July 21st, 1923, p. 132) could not doubt that they were true to type, and the photograph gave a convincing proof also of the efficacy of vaccination. Granted that the cases of small-pox in the Gloucester epidemic were mild, this only emphasises the necessity of insisting upon general vaccination. How often has one seen a mere blush of a rash in one child cause a fatal malignant scarlet fever in a contact. Compulsory notification of chicken-pox in times of small-pox prevalence, and in fact at normal times, is good, but it will be as ineffectual as the control of measles by notification if no action is taken. A routine procedure with chicken-pox notification, introduced by Dr. Joseph Priestley, M.O.H., Lambeth, S.W., is to offer vaccination to all cases and contacts, thus ensuring protection in the event of mistaken diagnosis. The use of carbolic oil during the scaling off of the pustules is another helpful measure. In 1922 there were 780,000 births in England and Wales, and 357,920 declarations of conscientious objection to vaccination. This is an appalling figure, and in some respects is not to be wondered at when it is known that even amongst medical men there is doubt, if not as to the efficacy of vaccination, then certainly as to the advisability of infant vaccination.

It is difficult to understand how medical men can be sceptical of the value of vaccination. Three cases recently reported from the Doncaster district under Dr. Arthur Briggs Dunne, the medical officer of health, are very convincing:—

> 1. In one house where a case occurred there were 10 unvaccinated contacts, eight being children, and nine of these were vaccinated after the case went to hospital; one of the children, the youngest, remaining unvaccinated. This child was the only one to contract the disease.
>
> 2. In another house two families were living in an overcrowded condition, and a case of small-pox occurred. Every member of this household was vaccinated within one hour of the patient being removed. Despite the overcrowding no other case occurred.
>
> 3. On the other hand, in a house containing eight contacts of a patient where vaccination was refused, five cases occurred, one after the other, until at last the father consented to have the remaining two children vaccinated.

The number of vaccinated persons varies considerably throughout the country. The percentage of children vaccinated in the following cities, for instance, is: Liverpool, 75; Manchester, 50; Sheffield, 43; and Leicester, 5. Dr. Killick Millard, the medical officer of health for Leicester, does not, I understand, recommend the routine compulsory vaccination of infants, but allows that general vaccination should be adopted in the event of the appearance of small-pox in a district. The figures seem to indicate in a striking manner the influence of the policy of the chief administrator in the public health service of any city or area. The trend of opinion, medical and lay, seems to be against infant vaccination. A resolution asking the Government to repeal the conscientious objection clause of the Vaccination Act was defeated recently by 14 votes to 11 at Hackney, London, E., Board of Guardians. There is no question that the inoculation of an infant with calf lymph does in many instances seriously disturb its metabolism. Popular objections are based on the undoubted suffering and illness, sometimes fatal, resulting from infant vaccination.

I consider that a compromise between the extreme pro- and anti-vaccinationists can be found in school vaccination. Probably the rigid old vaccination laws have done harm, but such harm is reparable. Anathematising by doctors of all people who will not submit their infants to vaccination can have but one result—namely, to make them more obstinate. Thus the scientific treatment of diseases like diphtheria and whooping-cough does suffer. The secret of the success of the public health service is a policy of educative tact and persuasion; thus and only thus can school vaccination and infant vaccination likewise be successful.

I submit that :—

(1) Every child should be vaccinated during its first and last years of school life, normally at ages 5 and 14.

(2) This work should be done by the school medical inspectors and nurses. The clinics and organisation are ready now for the emergency. An order from the Ministry of Health would set efficient machinery working quietly throughout the country.

A school medical inspector responsible for, say, 8000 children in 60 schools in an urban area, and proportionately more or less in a borough or county area, could vaccinate all the children twice in their school life. The risk of the probably unprotected three to five years of a child's life is compensated for by the mere thorough double school vaccination, and the absence of the possibility of injuring the health of the child by infant vaccination. The demand for school vaccination is making itself evident. During 1922, 25,313 children were vaccinated in the London County Council schools with the consent of their parents. I understand that the Oxfordshire Education Committee has recommended the Board of Education to consider steps to make vaccination obligatory upon all children to be admitted to or in attendance at a public elementary school or aided secondary school. Worcestershire and Derbyshire County Councils (*Public Health*, August, 1923) have made similar representations to the Ministry of Health. Mr. Neville Chamberlain, the late Minister of Health, said in Parliament that the responsibility for the administration of the Vaccination Act rested with the boards of guardians and their vaccination officers. He was not satisfied that the Act was being properly administered in all districts, and he was considering what steps could be taken to secure an improvement in that respect.

There has long been a feeling that vaccination could be more efficiently administered by its transfer from the Poor-law to the Public Health Medical Service. There have been 92 deaths from small-pox in Great Britain in the five years 1918–1922, and 48,107 in the period 1868–1872. There is no question that improved sanitation has had much to do with this reduction. That is all the greater reason why public health officials' hands should be strengthened. Sanitation cannot conquer an epidemic once it is raging. A step towards efficiency would be double school vaccination. There need be no more compulsion about it than there is in the present popular medical inspection and treatment of school children. It is gratifying that such a world-wide authority on vaccination as Dr. McVail should take the broad-minded view he does regarding the sincere objector to vaccination. Education in hygiene makes compulsion a thing of the past.—I am, Sir, yours faithfully,

S. NICOL GALBRAITH, M.B., D.P.H.

Tonbridge, Kent, Oct. 15th, 1923.

CONGENITAL MIOSIS.

To the Editor of THE LANCET.

SIR,—Concerning the three cases of congenital miosis published in my article Congenital Miosis or Pinhole Pupils Owing to Developmental Faults of the Dilator Muscle,[1] I see the following phrase in THE LANCET (Sept. 22nd, 1923, p. 614): "The anatomical explanation of the condition was pronounced to be the defective development of the dilator muscular fibres of the iris. As to this it might be objected that the dilator muscle of the iris is normally so slight in development that for many years its existence was doubted."

This doubt might be justified before the good technical methods for depigmentation of the iridial pigmentum epithelium were introduced by Alfieri in 1898; later came the hydrogenium dioxyd method. To-day anatomists would not agree with the quoted passage, finding the dilator muscle well developed from the pupillary margin to the ciliary border. This was the experience of my collaborator, O. Berner, examining the iris in 12 normal persons of different ages between 17 and 65. Only in some small spots—few and far between—the front epithelium cells are not transformed into muscular cells (v. Szily). In our two cases of congenital miosis, anatomically examined, the dilator did not exist in the periphery of the iris and was nearly absent in the intermediary part in one of them; in other words, the dilator had no peripheral anchorage. Thus the congenital miosis is well explained; the sphincter pupillæ had no functional antagonist. I tried in vain to detect a certain case of congenital miosis in the pedigree. The father was the only possible exception, but he did not allow the application of mydriatics (homatropin), which is necessary for a sure diagnosis The father's pupils were not 2·5 mm. in diameter, but "between 1·5 and 2 mm.," as I wrote in my article. Congenital pinhole pupils have been mistaken for spinal miosis. In the latter condition the pupil is seldom less than 2 mm. in diameter; in the former, as a rule, between 0·5 and 1 mm.

I am, Sir, yours faithfully,

Christiania, Norway, Oct. 8th, 1923. S. HOLTH.

THE DIATHERMY TREATMENT OF GONORRHŒA IN WOMEN.

To the Editor of THE LANCET.

SIR,—It is very pleasing to find that others are working at the treatment of gonorrhœal infections by using diathermy currents.

It is noticeable that the methods employed by Drs. Milner and Maclachlan differ from those we have used (see THE LANCET, Sept. 29th, 1923, p. 652). As a comparison of methods and results is likely to lead to improvement of technique this is advantageous. At St. Bartholomew's Hospital the treatment of gonorrhœa by diathermy currents has been carried on continuously since 1919, when it was recommenced after a lapse of time due to the war. It is a continuation of the work done by Dr. E. P. Cumberbatch from 1912 to 1914. A notice appears in his book on Diathermy, published in 1921, of what had up to that time been done. An account of technique and result was put before the Royal Society of Medicine by me in January, 1922.

There is one comment I should like to make if I may be allowed to do so. Our methods differ fundamentally in one particular—viz., in the means adopted to arrive at the dosage of current for the cervix. The authors of the article referred to state that "no diathermy electrode should be introduced into the urethra on any account." It is impossible to work with reliance on the readings of thermometers, although we have used special thermometer-electrodes to check results in regard to the temperatures obtained. The cervix being insensitive, how, then, are we to obtain the required dosage for it? During the last four years it has been my custom to introduce into the female urethra a metal electrode and by this means to apply the diathermy current. I have never known a burn of the urethra to occur. It is hardly to be conceived that without an anæsthetic a patient would allow a sufficient temperature to be reached to cause a burn. The sensation of heat changes to one of pain at about 115° F., but this is a long way from the temperature required to cause coagulation or even enough damage to blister. The urethra is no more liable to damage from heat than other structures. It is, in fact, less liable to be damaged than the skin on account of its smaller resistance. I have always used the female urethra to provide the index of the amount of current required for the treatment of the insensitive cervix. Thus in the urethra if 1 ampère is required to reach the point where the sensation of heat changes to one of pain, that is to say, just short of 115° F. with $1\frac{1}{2}$ in. of sound introduced, ·5 ampère passed through $\frac{3}{4}$ in. introduced into the cervix produces the same temperature. This I have found many times to be correct.

---

[1] British Journal of Ophthalmology, September, 1923, pp. 401–419.

If, as sometimes happens, 2 or 3 in. of electrode pass through the cervix into the uterus a corresponding amount of current must be passed.

To record the temperature in the cervix a special thermometer-electrode must be used. It cannot be done by stopping the treatment and then taking the temperature, as the loss of heat is too rapid. In the early days we had some slight burns but no harm has ever resulted. A burn of the cervix is no reason for stopping the treatment if care is taken not to superadd the effects of another burn.

We have been very interested in Drs. Milner and Maclachlan's results and are gratified that their results go to confirm our own.

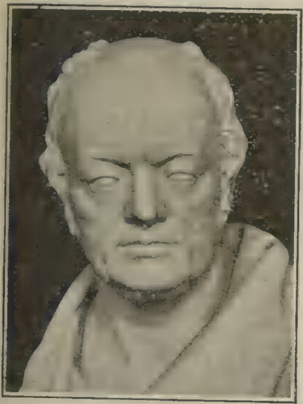
I am, Sir, yours faithfully,

Oct. 10th, 1923. C. A. ROBINSON.

AN UNIDENTIFIED PORTRAIT BUST.

To the Editor of THE LANCET.

SIR,—The accompanying photograph is of a bust in the museum of the Middlesex Hospital Medical School. We have made great efforts to find out who the bust represents, but we have never been able to do so. Possibly some reader of THE LANCET might be able to help us in identification. It has probably been in the medical school about 80 years. Inscribed on the back of the bust is the following:—



"Joseph Deare, Sculpt.,
Published 1832,
London."

I am, Sir, yours faithfully,

A. E. WEBB-JOHNSON,

Dean of the Middlesex Hospital Medical School.

Oct. 13th, 1923.

HEARTBURN.

To the Editor of THE LANCET.

SIR,—Although physiological experiment and accessory clinical methods have done much to advance our understanding of symptoms and their mode of production, there are still many subjective manifestations of ill-health for which no adequate explanation is forthcoming, and of which the treatment in consequence remains unsatisfactory. "Heartburn" is such a symptom. Probably most people experience it at some time in their lives; with others it is a frequent and distressing complaint. Apparently it may occur either in the presence or absence of an organic lesion; it may occur with or without other digestive symptoms; it may accompany the physiological disturbances of pregnancy in women who are never troubled with it at other times; radiography and chemical methods have failed to throw any conclusive light upon it; it is met with, I believe, in persons with achlorhydria as well as in persons with hyperchlorhydria; alkalies give relief, but this does not necessarily signify that abnormal acidity is a factor; it cannot be produced with solutions of hydrochloric acid; whether the organic acids found in the stomach can produce it I do not yet know; it is even disputed whether it expresses a mechanical or a chemical irregularity; and finally there is no absolute agreement as to what he symptom is, different persons employing the term o describe different sensations, or confusing "heartburn" with other gastro-œsophageal discomforts. "Acidity" and "cardialgia" are used as alternative descriptions. "Pyrosis," however, which should be synonymous, is employed to describe "water-brash," an entirely different phenomenon.

Obviously before we pursue its causes further we require more clinical information about the symptom itself, and the circumstances connected with it. In perusing Galton's "Enquiries into Human Faculty" recently, I was much struck by the interesting and sometimes valuable information which the author obtained in regard to certain mental phenomena by the process of circulating his inquiries to men and women of intelligence in scientific circles and to others likely to prove reliable observers. It occurred to me that it might be possible to accumulate useful information in regard to some of the commoner subjective symptoms by similarly circularising to medical men a questionnaire, to which those with personal experience might themselves provide the answers, while others gleaned them from their more intelligent and trustworthy patients.

If such a method should appeal to any readers of THE LANCET I would suggest that an attempt to secure answers to the appended questions be made, and would ask for the information to be forwarded to me at Guy's Hospital. Replies would, of course, be fully acknowledged, and names and addresses treated confidentially. A favourable response might serve not only to direct and stimulate further inquiry of an experimental kind, but also to pave the way for similar inquiries into allied problems of symptomatology. In addition, it would afford to colleagues in general practice an opportunity of coöperating in a piece of practical clinical research for which their observations would provide the basic material.

Questions Relating to "Heartburn."

1. What is the nature or character of the symptom?
2. How long have you been familiar with it?
3. At what vertical level or levels is it experienced?
4. At what depth from the body surface and over what surface area does it seem to be felt?
5. What is the maximum, minimum, and mean duration of the symptom?
6. What factors, if any, seem to initiate or aggravate the symptom?
7. Under what natural conditions does relief occur?
8. What artificial measures (e.g., drugs, &c.) bring relief?
9. What is the momentary effect on the symptom of swallowing: (*a*) Nothing; (*b*) hot fluids; (*c*) cold fluids; and (*d*) solids?
10. What associated symptoms have you noticed (e.g., flatulence, nausea, vomiting, salivation, gastric pain, regurgitation of food, bile, acid or bitter juice)?
11. Has a diagnosis of any organic disease ever been made or suggested in your case, and if so, on what evidence?
12. Have you been investigated by X rays with the opaque meal or by a test-meal, and if so, with what result?

I enclose my card, and am, Sir,

Yours faithfully,

SECRETARY OF THE HEARTBURN INVESTIGATION COMMITTEE, GUY'S HOSPITAL.

Oct. 9th, 1923.

INTESTINAL DISINFECTION.

To the Editor of THE LANCET.

SIR,—My attention has been called to the following statement made by Prof. Dixon of Cambridge, before the Pharmaceutical Society, as published in THE LANCET of Oct. 13th (p. 846): "Disinfectants have so far been ineffectual to diminish materially the intestinal flora—they poison the body before the bacteria." THE LANCET, in a laboratory report on April 9th, 1921, stated the claims of dimol, adding: "It is possible to destroy all bacteria in the fluid contents of the intestinal tract with a duodenal douche of dimol." If Prof. Dixon would care to have particulars of the method by which these results are obtained, he will find them in a brochure entitled "Colonic and Duodenal Lavage, with a Suggested Improvement in the Plombières Treatment" (London: H. K. Lewis and Co., Ltd.).

I am, Sir, yours faithfully,

J. T. AINSLIE WALKER.

Ludgate-hill, London, Oct. 13th, 1923.

Obituary.

SIR WILLIAM RICE EDWARDS, K.C.B., K.C.I.E., C.M.G., M.D. DURH., HON. F.R.C.S. EDIN., M.R.C.S. ENG.,

LATE DIRECTOR-GENERAL, I.M.S.

Major-General Sir William Rice Edwards, who retired from the Director-Generalship of the I.M.S. only a few weeks ago, died in London on Oct. 13th from pneumonia at the age of 61. He was the son of the late Canon H. P. Edwards, of Llandaff, and received his early education at Magdalen College School and Clifton. After studying medicine at the London Hospital, he obtained the M.R.C.S. Eng. in 1884 and graduated M.B. with honours at Durham University in the same year, proceeding to the M.D. degree two years later, when he entered the Indian Medical Service. He served on Lord Roberts's staff for four years and afterwards was surgeon to the Eden Hospital, Calcutta, and civil surgeon at Quetta, but during the South African War he rejoined Lord Roberts's staff as surgeon at headquarters. For his services he was mentioned in despatches, awarded the C.M.G., and received the Queen's medal with five clasps. In 1901 he was appointed superintending surgeon of the Kashmir State Hospitals, a post which he held for some ten years, and became subsequently chief medical officer of the North-West Provinces and Surgeon-General of Bengal. In 1917 Sir William Rice Edwards was appointed honorary surgeon to the King, and in the following year became Director-General of the Indian Medical Service. He received the K.C.I.E. in 1921. As a member of the Council of State of India, as a soldier, and as a doctor he was held in high esteem, for he was a careful and efficient administrator. His death at a comparatively early age is also a loss to international medicine, for on his retirement from the Director-Generalship of the Indian Medical Service he was appointed representative of the Government of India on the Permanent Committee of the International Bureau of Public Health.

MICHAEL THOMAS SADLER, M.D. LOND.

A DISTINGUISHED physician of an older generation has passed away in Dr. Michael Thomas Sadler, who died at Rugby on Oct. 11th in his ninetieth year. Dr. Sadler had practised medicine in Barnsley, Yorks, for 44 years. Born in 1834, he received his early education at Wesley College, Sheffield, and in 1853 graduated B.A. at London University. Four years later he passed his M.B. with honours, and in 1861 he obtained his M.D. London. His medical studies were pursued at Edinburgh University and at St. Bartholomew's Hospital, and he was a pupil at Barnsley of his own father, to whom Sir Thomas Spencer Wells was apprenticed. For many years he held the post of medical officer of health for the borough of Barnsley and the surrounding district. He held an appointment on the staff of the Beckett Hospital as physician, and had an extensive consulting practice in the West Riding. During his years of practice in Yorkshire he was a patient advocate of improvements in secondary education, and was deeply interested in public hygiene. After his retirement he gave much of his leisure to the work of the Charity Organisation Society. In 1860 he married Annie Eliza, daughter of John Adams, of Torrington, Lincolnshire. His great-uncle was Michael Thomas Sadler, of Leeds, Member of Parliament for Newark, social reformer and political economist.

In appreciation of Dr. Sadler, Dr. A. Maude writes:—

I was house physician at Barnsley to Dr. Sadler in 1885, and 40 years have not changed my opinion that he was one of the best physicians I ever worked under, or with. He was not merely a sound and careful practitioner, of large experience, but he was a great scholar of medicine. I had come to him fresh from two house physicians' posts and one house surgeon's, at hospitals in London, and Sadler taught me more medicine than any of my previous chiefs. Widely read as he was in French and German, as well as English, he was avid of new information. He would come to me in the morning and ask me to prepare by night a summary of all the literature I could find on some point bearing on some case in his private practice; and as we had a good library at the hospital, as well as his own collection of books, the task was exacting. But his digest of the material furnished was so illuminating that the labour was most profitable. Dr. Sadler also acted as gynæcologist to the hospital and was an admirable operator, taking great pains to adapt his technique to the changes required for aseptic work. I well remember his first ovariotomy at which I assisted, a case full of operative difficulties, which he met with minute care. He was a man of wide and careful reading in general letters, history, and philosophy, assiduous, within the limits of his leisure, on foreign travel, and his house was a valued centre of culture and hospitality.

Dr. Sadler leaves two sons and three daughters. His eldest son is Sir Michael Sadler, Master of University College, Oxford, and his second son Dr. F. J. Sadler, who carries on the family practice at Barnsley.

Medical News.

UNIVERSITY OF OXFORD.—The degree days in the present term are the following: Nov. 1st, 17th, and 29th, and Dec. 15th.

UNIVERSITY OF CAMBRIDGE.—At examinations held recently the following candidates were successful:—

SECOND EXAMINATION FOR MEDICAL AND SURGICAL DEGREES.

Part III., Pharmacology and General Pathology.—G. M. Addison, B. W. Alexander, H. M. Anstey, D. Aserman, G. H. Barendt, G. J. O. Bridgeman, C. F. Brockington, H. J. Burrows, R. D. W. Butler, J. W. D. Buttery, G. P. Chandler, R. Childs, A. C. Copley, A. T. Curnow, R. D. Curran, K. E. D. Dauncey, R. K. Debenham, H. V. Dicks, J. V. Dockray, A. G. Eddison, M. Escovar, E. S. Evans, M. G. Fitzgerald, L. Foulds, T. D. W. Fryer, R. Gallimore, S. E. Gawthrop, M. J. Harker, J. A. Hartley, A. S. Hollins, G. G. Holmes, W. G. S. Hopkirk, F. S. Hubbersty, I. A. Jackson, L. R. Janes, A. J. Johnson, C. E. Kellett, L. C. Lancaster, A. H. Lankester, D. F. Lawson, E. W. Lindeck, R. M. B. MacKenna, B. W. S. Mackenzie, W. K. McKinstry, W. S. Maclay, D. J. MacMyn, R. Marnham, R. W. L. May, H. L. Milles, G. C. Milner, J. K. Monro, J. W. Monro, W. J. Montague, J. K. Moore, H. E. Nourse, R. I. Osmaston, F. B. Parsons, L. V. Pearson, J. C. C. Poole, E. A. B. Pritchard, M. G. P. Reed, W. H. G. Reed, L. A. Richardson, M. E. D. Roberts, D. N. Rocyn-Jones, M. A. Rushton, W. A. H. Rushton, E. M. Sargant, H. J. A. Simmons, A. S. Smith, H. Smith, A. W. Spence, J. W. Stork, C. E. Taylor, G. F. Taylor, H. S. Taylor Young, R. S. Tooth, W. E. Underwood, R. Watson, J. G. Wigley, H. L. Wilson, F. G. Winterton, E. J. Worthington, and H. R. Youngman.

UNIVERSITY OF LONDON.—The Semon Lecture entitled the Advancement of Laryngology: A Plea for Adequate Training and Closer Coöperative Action will be given in the Lecture Hall of the Royal Society of Medicine (1, Wimpole-street, W.) by Mr. A. Logan Turner, at 5 P.M. on Nov. 1st.; the chair will be taken by Mr. Charles A. Parker.

UNIVERSITY OF BRISTOL.—Post-graduate demonstrations will be held at Swindon on Oct. 24th, when Mr. H. Chitty will discuss Infantile Paralysis, Ætiology, Stages, and Prevention of Deformities, and at Boscombe on Oct. 26th, when Dr. Walter Swayne will deal with Toxæmia of Pregnancy.

The annual dinner of the University of Bristol Association of Alumni (London branch) will be held on Nov. 9th, at 7.30 for 7.45 P.M., at Pagani's restaurant, 42–48, Great Portland-street, London, W. 1, Lord Haldane presiding. Tickets (8*s.* 6*d.*, exclusive of wines) may be obtained from Dr. E. Casson, Holloway Sanatorium, Virginia Water, Surrey.

UNIVERSITY OF GLASGOW.—The following degrees have been conferred:—

M.D.—With honours: John N. Cruickshank and Douglas M'Alpine (in absentiâ). With commendation: John M'Callum Lang, Alexandrena M. Maclennan, Charles L. Sutherland, and Walter Telfer. Ordinary degree: Kinloch Falconer, Alexander Fraser, and Henry J. Macbride.

M.B., Ch.B.—With honours: Benjamin G. Ives, Duncan L. Pow, and Alexander S. Henderson. With commendation: Andrew Meiklejohn, Janet M'Leod Stewart, Andrew M. Girvan, Moses Cohen, John M. Henderson, John M'Killop Fleming, Peter Shannon, Monica M. Bateman, James Gibb, Thomas W. Hill, Archibald M'Lellan. Ordinary degree: James H. Adam, James R. B. Alexander, Samuel M. Allan, Conway P. Allen, Isabella D. Anderson, Matthew C. Bain, Margaret A. Barr, Oliver F. Barr, Henry Baxter, John B. Bell, James S. Bizzett, John D. Black, Robert Black, Colin C. Blair, Harold W. Bowyer, Marion C. Boyd, W. Brown, William Brown, William M. Brown, Arthur Browning, Thomas W. Buchan, Ian M. Burdon, Alexander B. Burns, Joseph B. Bushe, Isabella E. Campbell, Patrick A. Carric, Evelyn L. Caskey, David L. Charters, Isobel M. Chisholm, Gilbert Cochrane, Samuel R. Costley, William Craig, George M. Currie, Lucie Leon van Dam, Alexander F. Davidson, Elsie B. Dickinson, James L. Dunlop, Andrew N. Fergus, James Fleming, Anne M. Forrest, James C. Fotheringham, Archibald L. Galbraith, Edward J. M. Gallagher, John E. Geddes, Eric G. Gerstenberg, James M. S. Gilbert, Joseph D. Young, and Jean L. Young.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At the monthly meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, held on Oct. 1st, the following were admitted, after examination, as Fellows :—

Margaret Hogg Grant, John Aitken Gilfillan, Alexander Reginald Lester, Colin William McRury, and Manuel Joseph Saldanha.

A bronze medal, specially struck in commemoration of the octo-centenary of St. Bartholomew's Hospital, has been presented to the Faculty by Dr. Alexander Macphail. The medal has on one side the head of Rahere, the founder of the hospital, and on the other William Harvey.

UNIVERSITY OF ST. ANDREWS.—At recent examinations the following candidates passed in the subjects indicated :—

THIRD PROFESSIONAL EXAMINATION FOR M.B., CH.B. DEGREES.

Materia Medica.—Alexander P. R. Borrowman, Barbara T. Cubitt, David C. Dickson, Davina M. Dingwall, Henry A. Graham, Janet L. M. Inglis, Crawford A. Lindsay, May A. Low, Janet E. Luke, Roberta G. McRae, Joseph H. Malloy, Mary E. Proudfoot, Renee Ritchie, Eric H. T. Rutherford, Raphael P. J. Rutherford, Bhavani Shanker, Jean R. Sheriffs, Robert W. Small, Jean J. Smith, Neil I. Smith, Karam Chand Virmani, and David D. Watson.

FOURTH PROFESSIONAL EXAMINATION FOR M.B., CH.B. DEGREES.

Medicine.—Andrew A. Finnigan, Jessie H. Fitchet, Alexander Henderson, James A. G. Keddie, Gordon D. Laing, Victoria R. L. Leslie, Ena M. Liddell, Francis McLagan, James R. Miller, Jermina M. Morrison, John R. Murray, Noel Nelson, Peter C. Robertson, Janet O. Stephen, and Gertrude J. Sturrock.

Surgery.—Colin R. Baxter, Thomas F. Black, Ellen Douglas, John R. Graham, Gordon D. Laing, Jeannie P. Laird, Victoria R. L. Leslie, Francis McLagan, John R. Murray, Peter C. Robertson, and Gertrude J. Sturrock.

Midwifery.—Monawar Khan Afridi, Colin R. Baxter, Thomas F. Black, Norman T. Brown, William F. Dorward, Lewis Farrell, Andrew A, Finnigan. Alexander Henderson, Lilian A. M. Johnston, Lutfur Rehman Khan, Gordon D. Laing, Jean R. Mason, James R. Miller, Noel Nelson, Peter C. Robertson, and Jainti Dass Saggar.

THIRD M.B., CH.B. DEGREE EXAMINATION.

Pathology.—Fakherddin El Ahmadi, Janet L. M. Inglis, Surendra Nath Lahiri, Mohan Lal, Rose M. B. Lee, Sydney C. McPherson, Ajudhia Nath Nanda, Robert Rutherford, Bhavani Shanker, Jean J. Smith, Neil I. Smith, and Karam Chand Virmani.

FIRST D.P.H. EXAMINATION.

Physics and Meteorology.—Frances Heron-Watson and James Lamberton.

FINAL L.D.S. EXAMINATION.

Dental Bacteriology and Operative Dental Surgery.—James T. Crighton.

Dental Surgery and Pathology.—James T. Crighton, John M. Laburn, and James Lindsay.

Surgery.—Alexander A. Galloway.

UNIVERSITY OF MANCHESTER.—The annual dinner for past and present students of the Medical School will be held at the Grand Hotel, Aytoun-street, on Nov. 8th, at 7.30 P.M. Tickets, price 15*s.* 6*d.*, may be obtained from the hon. secretary of the Dinner Committee at the Medical School.

TUBERCULOSIS SOCIETY.—A meeting will be held to-day, Friday, Oct. 19th, at 8 P.M., at the Margaret-street Hospital for Consumption, Margaret-street, London, W., when Dr. J. H. Sequeira will read a paper on Cutaneous Tuberculosis, illustrated by lantern slides.

HUNTERIAN SOCIETY.—The first dinner meeting will be held at Simpson's Restaurant, 2 and 3, Bird-in-Hand-court, 77 Poultry, Cheapside, on Oct. 22nd, at 7.30 P.M. (Price 3*s.* 6*d.* excluding wines.) After dinner, at 8.30 P.M., the presidential address on the Pitfalls of Medical Practice, will be delivered by Sir Bruce Bruce-Porter.

SCIENTIFIC AND INDUSTRIAL RESEARCH. — The report of the Committee of the Privy Council for Scientific and Industrial Research for the year 1922–23 has now been issued. The contents of the volume comprise the report of the committee, the report of the advisory council, a summary of the work of the research boards and committees of the department, and numerous appendices. The report (price 4*s.*) may be obtained in London at H.M. Stationery Office, at Imperial House, Kingsway, W.C. 2, or 28, Abingdon-street, S.W. 1.

EVOLUTION IN RELATION TO CHRISTIAN PRINCIPLES. A Medical Prayer Union meeting will be held, by invitation of Dr. Mary Scharlieb, at 149, Harley-street, London, W., on Oct. 25th, when an address will be given by Mr. A. Rendle Short on Evolution in Relation to Christian Principles. Those intending to be present should inform the hon. secretary, Dr. Tom Jays, Livingstone College, Leyton, London, E. 10.

CHADWICK PUBLIC LECTURES. — The following lectures will be delivered before the end of the year. In London : on Oct. 29th, 5.15 P.M., at the Medical Society of London, Chandos-street, Cavendish-square, the Disposal of the Dead, by Dr. C. Killick Millard ; on Nov. 9th, 16th, and 23rd, 8 P.M., at the Royal Society of Arts, John-street, Adelphi, Hygiene and Architecture, by Major Harry Barnes ; on Dec. 3rd, 8 P.M., at Goldsmiths' College Lecture Hall, New Cross, S.E., Housing Standards—How they can be Raised, by Dr. A. K. Chalmers, who will repeat the lecture on Dec. 5th at Kensington Town Hall. In Bristol, on Dec. 5th, at the University, the Theory and Reasonable Practice in the Disinfection and Disinfecting of Ships, by Dr. W. M. Willoughby. Further particulars of Chadwick lectures may be obtained from the Secretary, Chadwick Trust, 13, Great George-street, Westminster, S.W. 1.

AN INTERNATIONAL CLINIC OF PLASTIC SURGERY.—Arrangements are being made to supply a gap in the facilities for the practice and teaching of plastic surgery. It is proposed that a portion of the existing St. Andrew's Hospital at Dollis Hill should be utilised until funds are available to build another wing to the hospital to be devoted entirely to cases requiring plastic operations. Accommodation will be provided both for paying and free patients, the latter paying maintenance cost only whilst they are in hospital. A clinic will be held at the hospital and post-graduate classes will be arranged. The surgical and lecturing staff include the names of Mr. H. D. Gillies and Mr. T. Pomfret Kilner (Great Britain), Dr. J. Eastman Sheehan and Dr. Ferris N. Smith (America), and Prof. Lemaitre (France), all being well-known workers along this special line.

It is estimated that a sum of about £25,000 will be required. Donations should be made out to "International Clinic of Plastic Surgery," St. Andrew's Hospital, Dollis Hill a/c, London, N., and forwarded to the London Joint City and Midland Bank, 69, Pall Mall, London, S.W. 1, where a special account has been opened.

National Council for Combating Venereal Diseases.—An extraordinary general meeting of the Council will be held at 2.30 p.m., on Nov. 8th, at 1, Wimpole-street, London, W. 1. Items on the preliminary agenda issued are the definition of the policy of the Council *re* child assault, the provision of literature and publicity material on the subject of character training in its relation to sex control (resolution to follow), and the consideration of a resolution in which coöperation is suggested with the Government of India in helping the formation of an All-India Council for Combating Venereal Diseases.

During the last few days two out of the three more important German medical journals have suspended publication. The *Deutsche Medizinische Wochenschrift* and the *Medizinische Klinik* have ceased to appear, while the *Münchener Medizinische Wochenschrift* remains. The *Deutsche Medizinische Wochenschrift* was founded in 1874 by Dr. Pau Börner, and the *Medizinische Klinik*, which is the organ of the Berlin Medical Society and recently incorporated the *Berliner Klinische Wochenschrift*, has been appearing weekly for the past 19 years.

Conference of Cremation Authorities. — By invitation of the Lord Mayor of Liverpool, the Cremation Society of England will hold a conference at the Town Hall, Liverpool, at 3 p.m. on Oct. 25th, Dr. H. T. Herring in the chair. The following are already settled as subjects for discussion: Cremation Propaganda; the desirability of forming a federation of cremation authorities, by affiliation of each cremation authority with the Cremation Society of England, or otherwise; the issue of certificates during lifetime for subsequent cremation at death; issue of quarterly bulletin to cremation authorities; combined propaganda issued on behalf of the cremation authorities; and future conference arrangements.

Refugees in the Near East.—Dr. Fridtjof Nansen (High Commissioner for Refugees of the League of Nations) will speak on the Near East refugee question at the Central Hall, Westminster, on Oct. 24th, at 8.30 p.m. The Duke of Atholl will preside; during the course of the evening Miss Maude Royden will speak, and a specially-prepared film which has just reached this country will be exhibited. The meeting has been organised under the auspices of the All-British Appeal for the Near East, and applications for tickets should be made to the Save the Children Fund, 42, Langham-street, W. 1, or to the Imperial War Relief Fund, General Buildings, W.C. 2. Admission is free, but a limited number of seats are being reserved and applications for these should be accompanied by a remittance of 2*s.* 6*d.*

The Journal of Scientific Instruments.—A new monthly publication dealing with the principles, construction, and use of scientific instruments has been produced by the Institute of Physics, with the coöperation of the National Physical Laboratory. The first number contains the following articles: The Measurement of True Height by Aneroid, by L. N. G. Filon, F.R.S.; Two New Methods of Measuring the Internal Diameters of Transparent Tubes, by J. S. Anderson, D.Sc., and Guy Barr, D.Sc.; On An Improved Temperature Control for the Pulfrich Refractometer, by T. M. Lowry, F.R.S., and R. G. Parker, B.Sc.; a New Relay and its Application to Sustaining Pendulum Vibrations, by H. A. Thomas, M.Sc.; a General-Purpose Recording Drum, by C. V. Boys, F.R.S.; the Chain Balance, by Sir Flinders Petrie, F.R.S.; and a New Recording Kata-Thermometer, by E. H. J. Schuster, D.Sc., besides miscellanea and reviews. The journal will be published on the 15th of each month at 2*s.* 6*d.* a number, and the annual subscription is 30*s.* post free. Copies of the journal may be obtained through any bookseller, or direct from the Institute of Physics, 10, Essex-street, London, W.C. 2.

The late Dr. J. R. S. Robertson.—Dr. John Robert Stevenson Robertson, who died in London on Sept. 26th at the age of 64, received his medical education at the University of Edinburgh, graduating M.B., C.M., in 1881. From 1883 to 1888 he served as an army surgeon, being attached to the Guards; he received the Egyptian War Medal and the Khedive's Bronze Star. At the battle of Abu Klea in 1885 Dr. Robertson was in the square beside General F. G. Burnaby, when the latter died of his mortal wound. After retiring from the service, with the rank of colonel, he practised at Southsea, and later gave up professional work and moved to Hayling Island, where he took a great interest in local affairs—for example, in the campaign against mosquitoes, which was there carried out. Dr. Robertson was a keen golf and tennis player. A colleague describes him as "a very pleasant companion, full of good humour, and pleasant stories and reminiscences." Dr. Robertson suffered a great loss during the war in the death on active service of his elder son. His widow and younger son survive him.

Medical Golfing Society.—The autumn meeting was held at Rye Golf Club on Oct. 13th and 14th. Much appreciation was expressed of the hospitality and kindness shown to the society by the officials and members of the club. The results of the competitions were as follows:—Canny-Ryall Challenge Cup: H. P. Aubrey, 85 − 10 = 75; H. D. Gillies, 74 + 3 = 77; H. Wolseley Lewis, 85 − 7 = 78; T. P. Kolesar, 76 + 3 = 79. Scratch *v.* Bogey (under handicap): Sir K. Goadby, 2 down; H. Wolesley Lewis, 4 down. The Foursomes *v.* Bogey Competition under handicap ended in a tie between H. A. Richards and W Gilliatt, and W. L. Lamplough and H. D. Gillies.

Chelsea Clinical Society.—The programme of the twenty-seventh session is as follows:—Oct. 30th: Annual dinner at the Café Royal. Nov. 20th: Discussion on the Treatment of the Failing Heart. Opener: Sir Sydney Russell-Wells. Dec. 18th: The Manipulative Treatment of Joint Diseases. Opener: Mr. Frank Romer. Jan. 15th, 1924: The Treatment of Functional Nervous Disorders. Opener: Dr. S. A. Kinnier Wilson. Feb. 19th: The Treatment of Common Eye Disorders. Opener: Mr. Ernest Clarke. March 18th: The Treatment of Painful Menstrual Disorders. Opener: Dr. T. W. Eden. April 15th: Clinical meeting. May 20th: The Treatment of Non-Venereal Genito-Urinary Diseases. Opener: Sir John Thomson-Walker. Preceded at 8 o'clock by the annual meeting.

National Milk Conference.—A conference to discuss the different aspects of pasteurisation will be held in the Council Chamber of the Guildhall, London, E.C., on Nov. 21st. In the morning Lord Astor will preside. A paper on Methods and Processes of Pasteurisation will be read by Mr. Richard Seligman, and a discussion will be opened by Mr. P. B. Tustin. Physical Changes will be the subject of an address by Mr. A. T. R. Mattick, and Prof. H. R. Kenwood will open the discussion. Dr. S. B. Schryver will deal with Chemical Changes and Mr. G. W. Monier Williams, followed by Captain John Golding, will open the discussion. In the afternoon, Lord Dawson presiding, Prof. J. M. Beattie will read a paper on Bacteriological Changes, followed by Captain S. R. Douglas, F.R.S., Dr. Thomas Orr, and Mr. R. Stenhouse Williams. Prof. F. G. Hopkins, F.R.S., will then deal with Biochemical Changes. Dr. Harriette Chick will open the discussion, followed by Dr. S. S. Zilva and Captain W. E. Elliot. Finally, Financial and Commercial Aspects of Pasteurisation will be discussed by Mr. J. H. Maggs and Mr. G. Cecil Jones. Further particulars can be obtained from Miss H. M. Willans, hon. sec., National Milk Conference, 3, Bedford-square, London, W.C. 1.

Appointments.

Macnair, R. A. C., has been appointed Assistant Resident Medical Officer, the Warwickshire King Edward VII. Memorial Sanatorium.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Oct. 22nd.

ODONTOLOGY: at 8 P.M.
Presidential Address:
By Mr. Douglas Gabell.
Casual Communications:
Mr. E. B. Dowsett: An Interesting Case of Rarefying Periodontitis.
Mr. H. C. Malleson.

Tuesday, Oct. 23rd.

MEDICINE: at *St. Mary's Hospital, Paddington, W.*
5.15 P.M.—*Introductory Address:*
By the President, Dr. Robert Hutchison.
5.30 P.M.—*Short Papers:*
Prof. F. S. Langmead and Dr. E. C. B. Calvert: Cases of Obesity in Children (Hypopituitarism) with Some Investigations into their Carbohydrate Metabolism.
Dr. C. M. Wilson: Exophthalmic Goitre.
Demonstration: (time permitting)
Dr. A. C. Alport: A New Method of Blood-letting.
Selected cases of interest will also be demonstrated.
Tea will be served at 4.45 P.M.

Wednesday, Oct. 24th.

COMPARATIVE MEDICINE: at 5 P.M.
Introductory Address:
By the President, Sir Clifford Allbutt.
Paper:
Mr. Frederick Hobday: Cryptorchidism in Animals and Man (with illustrations and specimens taken from over 1200 cases).
A discussion will follow, to be opened by Mr. W. McAdam Eccles.

Thursday, Oct. 25th.

UROLOGY: at 8.30 P.M.
Presidential Address:
Dr. Langdon Brown: The Influence of Endocrines on the Work of the Kidney.
To be followed by a discussion.

VICTOR HORSLEY MEMORIAL LECTURE: at 5 P.M.
The First Lecture on the Relations between Surgery and Physiology, will be given by Sir Edward Sharpey Schafer, F.R.S., in the Barnes Hall. The chair will be taken by Sir John Bland-Sutton.

Friday, Oct. 26th.

STUDY OF DISEASE IN CHILDREN: at 5 P.M. (Cases at 4.30 P.M.)
Cases:
Mr. J. P. Lockhart-Mummery: Hemihypertrophy, traced from 5 years of age up to the age of 21.
Other cases will be shown.

EPIDEMIOLOGY AND STATE MEDICINE: at 8 P.M.
Paper:
Dr. W. Perceval Yetts: Pestilence and Leechcraft in Ancient China (illustrated with lantern slides).

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. 1.
MONDAY, Oct. 22nd.—8.30 P.M., Clinical evening: Exhibition of Cases and Radiograms.

HUNTERIAN SOCIETY.
MONDAY, Oct. 22nd.—Dinner at Simpson's Restaurant, Cheapside, 7.30 P.M. Presidential Address by Sir H. E. Bruce Bruce-Porter: The Pitfalls of Medical Practice.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, Oct. 22nd.—10 A.M., Mr. Maingot: Surgical Pathology. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.

TUESDAY.—10.30 A.M., Dr. Paterson: Medical Wards. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.

WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 11 A.M., Mr. Simson: Gynæcological Demonstration. 3 P.M., Dr. Pernet: Skin Dept.

THURSDAY.—12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Bishop Harman: Eye Dept. 3 P.M., Dr. Scott Pinchin: Medical Out-patients.

FRIDAY.—12 noon, Mr. Endean: Venereal Diseases. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept. 2 P.M., Mr. Sinclair: Surgical Out-patients.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, Marylebone, W. 1.

Intensive Course in Cardiology. (Conclusion.) Mornings 10 and 11.15 A.M.; afternoons 2 and 3 P.M. Saturday in the forenoon only.

MONDAY, Oct. 22nd.—Dr. B. T. Parsons-Smith: The Electrocardiograph. Dr. F. W. Price: Diseases of the Myocardium. Dr. R. O. Moon: Ward Demonstration. Dr. J. Strickland Goodall: Out-patients.

TUESDAY.—Dr. B. T. Parsons-Smith: The Treatment of Auricular Fibrillation. Dr. R. O. Moon: Congenital Heart Disease. Dr. F. W. Price: Ward Demonstration. Sir S. Russell-Wells: Out-patients.

WEDNESDAY.—Dr. F. W. Price: Diseases of the Arteries. Dr. P. Hamill: Treatment in Heart Disease. Dr. H. B. Weir: Pathological Demonstration. Dr. R. O. Moon: Out-patients.

THURSDAY.—Dr. R. O. Moon: Prognosis in Heart Disease. Dr. J. Strickland Goodall: Aortic Disease. Dr. B. T. Parsons-Smith: Ward Demonstration. Dr. F. W. Price: Out-patients.

FRIDAY.—Dr. J. Strickland Goodall: Blood Pressure and its Significance. Dr. John Parkinson: The Early Symptoms of Heart Failure. Sir S. Russell-Wells: Ward Demonstration. Dr. John Parkinson: Out-patients.

SATURDAY.—Dr. P. Hamill: Ward Demonstration.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: OCTOBER–NOVEMBER, 1923.

CLINICAL LECTURES AND DEMONSTRATIONS.

MONDAY, Oct. 22nd.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Disorders of Emotional Expression: Dr. Kinnier Wilson.

TUESDAY, Oct. 23rd.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Muscular Atrophies: Dr. Adie.

THURSDAY, Oct. 25th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Cerebral Tumours: Dr. Gordon Holmes.

FRIDAY, Oct. 26th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Labyrinthine Disorders: Mr. Sidney Scott.

COURSE OF LECTURES AND DEMONSTRATIONS ON NEURO-PATHOLOGY.

MONDAY, Oct. 22nd.—12 noon, Cerebro-spinal Fluid Pathology: Dr. J. Godwin Greenfield.

A COURSE of LECTURES on the ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM commenced on Oct. 16th.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

The fee for the Course, including Pathology, is £5 5*s*. The fee for the Anatomy and Physiology Lectures is £3 3*s*. If taken in conjunction with the Clinical and Pathological Courses, an inclusive fee of £7 7*s*. will be charged. Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course.

C. M. HINDS HOWELL, Dean of Medical School.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

TUESDAY, Oct. 23rd.—5 P.M., Dr. J. H. Sequeira: Tuberculosis of the Skin.

THURSDAY.—Dr. W. K. Sibley: Special Methods of Treatment.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Oct. 25th.—4 P.M., Mr. Higgins: The Treatment of Otorrhœa.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, Oct. 23rd.—4.15 P.M., Dr. C. H. Melland: Some Functional Nervous Conditions.

FRIDAY.—4.15 P.M., Dr. F. Craven Moore: The Modern Conception of the Investigation of Dyspepsia.

ANCOATS HOSPITAL.

(Special Course on Surgical Tuberculosis.)

THURSDAY, Oct. 25th.—4.30 P.M., Mr. E. E. Hughes: Abdominal Tuberculosis.

LIVERPOOL UNIVERSITY CLINICAL SCHOOL.

(At 3.30 P.M. each day.)

MONDAY, Oct. 22nd.—(At the Children's Hospital.) Dr. Hubert Armstrong: Clinical.

TUESDAY.—(At the Southern Hospital.) Dr. Johnson: Desseminated Sclerosis.

WEDNESDAY.—(At the Northern Hospital.) Dr. Bigland: Neurological Cases with Special Reference to Neurosyphilis.

THURSDAY.—(At the Stanley Hospital.) Miss Ivens: Some Causes of Pelvic Infection.

FRIDAY.—(At the Royal Infirmary.) Dr. Hay: Digitalis.

Notes, Comments, and Abstracts.

VILLAGE SETTLEMENTS FOR THE CONSUMPTIVE.

SOME ECONOMIC CONSIDERATIONS OF "TRAINING."

BY P. C. VARRIER-JONES, M.A. CAMB., M.R.C.S., L.R.C.P. LOND.,

AND

THE RIGHT HON. SIR CLIFFORD ALLBUTT, P.C., K.C.B., M.A., LL.D., M.D., F.R.C.P., F.R.S.

INTEREST in the development of the Papworth Village Settlement (so called for the want of a better name) seems unabated; indeed, the number of inquiries, far from becoming less, grows daily in volume. As the principles on which the scheme is founded become more widely and better known, so the advocates become greater in number, and the inquiries of those, whose interest is for the first time aroused, become more incessant. We have from time to time set forth our views on this subject, and in general terms explained, as best we could, the ideas which underlie the colony scheme; but we fear that our explanations have not as yet been sufficiently clear, or our articles, and the book by one of us, have not been read. We have thought, therefore, that some advantage may be gained by a further discussion of the principles which underlie the gradual growth of the village settlement, of how and why the evolution took place, and of the grounds of its success and its immense advantages, not only to the victims of consumption, but also for the safety of those who belong to the healthy world.

It seems that only by reiteration can the truth of a proposition be driven home; if then we go over the ground once again it is not only that we must, but also because it is only by a proper understanding of each step in the advance of the crusade against tuberculosis that success can be obtained. We have lately seen a prospectus in which, for example, it is stated that training is provided for the consumptive ex-soldier in the art of the blacksmith. Let us for a minute examine this proposition. Are we in all seriousness asked to suppose that a tuberculous ex-soldier—i.e., a man who has been discharged from the army with tuberculosis of the lungs caused or aggravated by military service—may, after a period of training, be made into a blacksmith? The armistice took place in November, 1918; the diagnosis of tuberculosis must have been made before that date. When, therefore, after the lapse of three to five years the man is to receive this instruction, there can be no probability of his disease being in an early stage. Whether meanwhile he has received sanatorium treatment or not, work at the open forge is no light job for such a patient, even if the technique of the business could be mastered.

When are we going to bring some common sense to the solution of the problem? It may be said that we have selected a ridiculous example; and, to the credit of the institution, it must be confessed that although it was stated in the prospectus that skilled instructors were available for various trades, including the particular one under consideration, not only had no instructor been appointed, but there was no smithy nor tools for that instruction; which is something to the good.

However, similar statements are made about farming; let the following be an example: "The institution gives instruction in market gardening, including bee-keeping, poultry farming, and pig rearing"—an ambitious programme; yet where is the man, after this training, to find the capital sufficient to establish the business? Then again, "The second course trains men in 'light farming'" (whatever that may mean—the occupation is unknown in the agricultural world), but it confesses that though the dairy side of the farm has to be done by healthy workers, yet "most of the rest of the work, such as hay-making, digging, hoeing, and weeding, can be undertaken by convalescents." What man will get work on a farm if he is to pick and choose his job? What wage is he likely to get for part-time work when the full agricultural wage for a skilled agricultural worker (and he has been "trained") is 25*s*. a week? The truth is, the light job in the open air is a myth, and its advocates are false prophets.

But what is behind the idea of training a consumptive for a short time and then letting him take his chance in the world at large? A partly trained man—such as, at the end of six months, the patient is—is put to compete with the healthy fully trained worker, whether it be in the factory, or on the land, or in any other occupation where labour has to conform to the economic law, will find himself utterly outclassed. Playing at a trade is not learning a trade; and ninety-nine out of a hundred of the trainees in these training centres are well aware that the position is an impossible one. In the majority of cases, what was described to us by an official of one of the Ministries as "the blessed state of the infinity of training," fairly sums the matter up. This masquerade is not altogether the patient's fault. If a man sees that the system is obviously wrong, so wrong that the ordinary working man can see its futility, can we blame him if he takes full advantage of "the blessed infinity of training" and goes from one training colony to another, "learning" for six months now this trade and now that, qualifying for a full pension for the following six months, and, when that period comes to an end, making application for, and being sent by another tuberculosis officer to, another colony for a further period of training in some quite different occupation. So far, experience shows that the tuberculous ex-soldier fails to obtain the full advantages proposed to him; he is put off witb a worthless scheme.

One has only to make a tour of various institutions—the so-called training colonies—to be convinced that the training given is of little worth to enable the pensioner to "*earn his living once more.*" A temporary benefit certainly accrues from living under proper conditions, and by being given some technical instruction to occupy his time. But to play with a trade is one thing, to learn it sufficiently well to earn a living is another. It is true that to be set to some work is certainly better than the dull monotonous routine of the sanatorium, and in this respect it is a step forward; but let it not be supposed that we are thereby training a man to earn his living. The moral fibre is improved, but the mental, bodily, and manual preparation is insufficient equipment for a livelihood. The whole purpose of treatment of any disease whatsoever is to restore the patient's earning capacity so fully as to enable him to become either self-supporting, or as nearly so as possible. But the course of training usually prescribed, we maintain, is too short to be adequate for this purpose. We are attempting the impossible. Can a man with a disability of varying intensity—hardly ever less than 50 per cent. and too often more—(we are now speaking of the ex-soldier or pensioner) and at the age of 30 or over, learn a new technical trade, whatsoever it may be, so well as to compete with the 100 per cent. man who by long apprenticeship has a full and complete knowledge of that trade? Let us take a definite instance which has come to the notice of one of us. A young clerk in a training colony was asked, "Why did you give up clerking?" He answered that on account of his disability the firm he used to work for would not give him shorter hours; he was expected to work full time, or not be employed at all. This is, of course, only too common. The economic world will not support an unearning unit. A man who is unable to work economically must fall out. Against the hard economic fact our clerk had come up; he availed himself therefore of training in a new occupation for two reasons: (1) That during his training his pension allowances were increased to 100 per cent., and (2) he had free board and lodging. This was certainly an improvement on his pension of 30 per cent., which was the assessment of his disability. He had decided therefore to learn watch-repairing—the prospectus said, "watch-making and repairing"; but a moment's thought will convince anyone that watch-making is now carried on in factories where such an uncertain worker could not hope for a place. Watch-repairing seems at first sight to be a light trade easily taught and easily learned; but talk for a few minutes to an experienced watch and clock repairer and you will hear another story: First, one must recognise the peril of placing a consumptive, probably with others, in a tiny workshop which must be heated, as cold hands cannot manipulate small tools and small parts; secondly, the inexperience of the worker will make his employment utterly unremunerative to the employer. It must be remembered also that the watch and clock repairing trade is largely in the hands of Swiss and other foreign workers, labour which is cheaper and more highly skilled than any that can be turned out of the training centres.

What, then, was this clerk going to do at the end of his training? His answer was, "I am to have a little money when this training is over, and then I shall set up on my own." Where? He did not know. No doubt he pictured to himself a sunny English village, a shop and house already waiting to be occupied (he had not heard of the housing shortage), and populace willing and anxious to send in all their repairs, and a grant for stock-in-trade—a matter of £50 at the outside. Had he any experience of business? None. Had he thought of furnishing his house, or of times of relapse when his business would have to be carried on by an assistant?

When are we going to construct on knowledge a sound appreciation of the patient's medical condition, the bearing this has on his earning capacity, the conditions under which this capacity can be restored, and, finally, the help which is necessary and practicable? The old plausible advice, "Seek a light job in the open air," is on a par with the case above quoted. The same arguments apply, and the same misfortunes follow. The working-class consumptive cannot compete in the open labour market, even at his own trade, much less in a trade of which he has but a superficial knowledge. Are we to believe that a man can be trained in an occupation for six months and then be fit to compete with his fellow-workers in that particular trade, not to mention his restoration to health? Let us inquire of any skilled artisan, or any employer in any trade or profession, and we shall find the answer to be the same every time. In discussing the teaching and training of a city-bred man in farm work for a space of six months or so, we said [1] that the chances of success in such a change of employment were slender; and since then we have had no reason to modify our opinion. We said that "the unskilled hand, the untrained eye, and the inexperienced brain are of little use to the farmer and certainly cannot be profitably employed."

Those who ask us how many men can be trained in agriculture in the course of six months can have no idea of the tuberculosis problem or of its bearing upon the study of economics. "A genuine case of pulmonary tuberculosis, with a definite and progressive lung lesion, will undoubtedly benefit by a prolonged stay under ideal colony conditions; but ultimately very few will be able to stand alone, and, working from morning till night, to live on the produce of a small holding. The arrest of the disease is so imperfect and the conditions so unstable that the proposition cannot be a paying one; from a medical point of view alone, apart from economic and psychological factors, this instability is the main cause of failure, and must necessarily remain so until some method of stabilising the arrest is attained." Again, we said that "even a few months spent in specially fitted up shops at a colony is quite inadequate to qualify a patient to obtain his admission into any skilled trade and into the corresponding trade-union, even should he have at the end of the limited period of training the ability to perform the work." The truth is, the factory or a general workshop is no place for such a man. The pace required is too great; at once, or in a short time, he collapses under the mental, physical, and economic strain.

Now how does this experience compare with that gained by watching those who remain under *settlement* conditions at a village settlement? Here the fundamental factors—viz., the physical, mental, and economic—are materially altered. Let us consider the difference between "training" a tuberculous worker in a trade which it is impossible for him to follow under ordinary commercial conditions, and the "training" of a similar worker to *earn his living* under settlement conditions. The adverse factors which are responsible for the breakdown of the tuberculous worker in the commercial world are under settlement conditions eliminated. The stress and strain, the economic pressure, is reduced to a degree that he can bear. In other words, he is protected from the burden of competition. It is true that the industries of the settlement are run as business concerns—that is, they enable the worker to earn "his living," but the workers in the outside world, beside earning their own living, have to contribute to the interest on the capital for running those industries, and to the costs of management. At Papworth, by experience and experiment, it is found that this contribution is just what a consumptive is unable to make; he is unable to earn enough for large overhead charges and for a dividend for his employer. For these reasons a consumptive cannot be employed in a money-making concern, and we see why all employers "turn down" applications for employment by consumptives. But under suitable conditions the consumptive can and does earn his own living, and earns it fairly well. Is this not then the plan for further progress in the tuberculosis campaign?

The industries of the Papworth Colony are run as several concerns in order to see what happens economically when a consumptive is trained in a new occupation, to prevent confusion of results, and also to obtain a clear picture of the working of each industry, and its adaptability or otherwise to the needs of the consumptive. Moreover, each business is run, as far as possible, on commercial lines, all those features being retained which we are accustomed to look upon as essential to industry, and which the working man more especially regards as essential to his own service; for obviously one of the first questions a "prospective" settler asks himself is, "How far is this industry a going concern?" "Is it likely to pay me the wage to which I think I am entitled?" "Is it carried on in a business-like manner, for if not it will not succeed, and I shall be commercially stranded?" Having satisfied himself on these points, and being assured that the particular industry he selects can pay him a certain wage if he earns it, he next inquires as to the further subsidy which he knows will be necessary in order to secure the maintenance of his health and sufficient means to keep himself and his family. If these conditions are assured, the man no longer hesitates to throw in his lot with the village settlement.

---

[1] THE LANCET, 1919, ii., 526.

Surely, then, these are matters for careful thought on the part of those in authority. The workings of the mind of the prospective settler must be studied. One man, it is true, may not give as much time and thought to these questions as another, but on the whole the trend of thought is much the same in each case; and men discuss their conditions with each other. With the right sort of man, the man who will try his best to benefit by the unique opportunity offered him, it is an easy matter to calculate his ability to perform a certain task, the time which he will take to do it, and the fruits of his labour. We have now collected facts and figures to prove that the consumptive can earn a wage sufficient, together with a small subsidy, to provide the necessaries of life for himself and his family. He is no longer to be a drag on the general community; no longer is he to serve as a source of infection either to his family or to his fellows. For the after-care committees he becomes a productive unit. These committees have sometimes, it is true, to deal with a different kind of man.

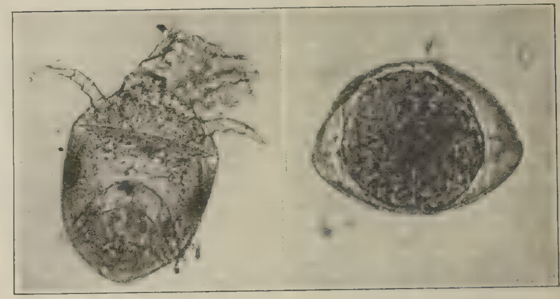
There is, of course, another type of man, who views the matter from an entirely different standpoint. He has no liking for industry; he tries his best when at home to escape that thraldom, and regards with suspicion the introduction of any such system into a sanatorium, which he supposes to be a place of holiday provided free by the State. He has no desire to "get well," lest his working capacity being restored his pension should be lost. To do a little work when he feels inclined, in his own way, at his own time, and at a job which he fancies, is exactly what he wants. He may not be inherently lazy, but he does not wish to be under any control or fettered by any kind of rules. This is unhappily the feeling which prompts so many ex-Service men to desire training in, e.g., boot-repairing, so that they may return home, set up a small business, and do as they like. These men have one fear, and one only—that is, lest, if they are not very careful, they may lose their pensions. So, again, the request to be set up in a small way of business as a dealer, or as a small shopkeeper, has the same motive behind it, a motive by no means confined to consumptives. The desire to escape from the monotony of industrial life, to live as one chooses or as others may seem to be doing, is an idea firmly fixed in the minds of a large number of ex-soldiers, but happily it is a diminishing one. The great upheaval caused by the war partly accounts for this perversion; the nation as a whole is waking up from similar dreams. Just as we were promised first-class hotels for consumptives, so we were told that immediately after the war a higher standard of living would be provided for all, without too much exertion or effort. We all know the fate of such dreaming. But gradually the economic position has become clearer and, just as the light open-air job promised by countless physicians is an economic failure in so far as the consumptive working man is concerned, so also the notion of a rapid intensive industrial training for the consumptive is a fallacy even more harmful.

A PLEA FOR A COLLEGE OF ENTOMOLOGY.

In an interesting article[1] on the Growing Importance of Entomology Dr. H. S. Fremlin points out that to most collectors entomology means collecting butterflies and moths, getting as many species of these as possible, having good series and as many varieties as one is able to obtain. To such a one the Bath White and the Camberwell Beauty are always looked-for prizes, and the mind turns now and then with longing to a Clifton Nonpareil, or a Crimson Speckled Footman; to all the Large Copper is a gem in the collection, even though it must be obtained at a shop. There are other collectors who hunt for beetles, or dragonflies, or bees, and here and there one who works for grasshoppers or earwigs; but these are few. Yet the real importance of entomology in the world is dependent on the great influence of insects in the vegetable kingdom and on the part insects take in the causation of disease. Insects may carry destruction into the vegetable world, and disease and death into the animal kingdom; this great multitude of butterflies, moths, wasps, flies, grasshoppers, beetles, aphides, mosquitoes, midges, fleas, thrips, lice, and so on, coming into existence every day and rising as a cloud over the earth, these are to be controlled, the friends improved and multiplied, and the enemies hunted out and destroyed. A large amount of good work is being done by entomological societies in training collectors, but Dr. Fremlin deplores the lack of central organisation. Entomology has to be taken up as a hobby, or learned by those who are necessarily brought in contact with insect pests, as gardeners, or as agriculturists. He urges the need of the formation of a College of Entomology, where men are trained in all branches of this subject, where insects and their parasites are investigated, where insect blights of individual species of plants growing in various parts of the world could have the pests and their parasites studied, where arrangements could be made to distribute useful parasites. This central body should, he considers, be linked up with stations in all parts of the world to give advice, examine specimens, and receive reports. Investigations carried out in the tropics on pests or disease-producing insects should be notified, and when necessary experts could be sent out to assist the investigator. Inspectors should also form part of the central staff to assist in training the public by lectures, advice, and practical help. A definite system of training should be required of all who were members of this College. They should have a general knowledge of all orders of insects and make a specialty of one. They should also have a good knowledge of botany, which is essential in connexion with vegetable blights, and of chemistry, so necessary in dealing with insecticides both in their preparation, use, and, where necessary, analysis.

A NEW SKIN GAME.

"Astonishing what people *will* carry about with them unawares," said the keeper of the Magic Shop in Mr. H. G. Wells's tale. At the Chilprufe Mills, Leicester, is a department to which wearers of these underclothes may send their worn garments for renovation. In this department Mr. John A. Bolton is conducting an investigation into the causes of the "felting" of underwear and, although he has not come across the "little wriggling red demon" of the tale, his investigations have brought to light a sufficiently varied collection of odds and ends. These were revealed by the microscopic examination of the sediment left in the water after the cleansing process, and include such trifles as the shells of bed-bugs, larval fleas, ova of various sorts, more particularly those of Ascaris and *Trichiuris trichiura*, adult ascarides, segments of tapeworms, desmids, and the hyphæ of moulds. The underwear of one child, the only one in the family which felted its woollens, was found to contain numerous granules of starch; an injudicious use of dusting powder at once presents itself to the mind, but it is possibly significant that the father of this child died of diabetes. One is reminded of the late Sir William Osler's tale of the ailing child of wealthy parents; it was before the days of vitamins and a numerous flock of consultants stood baffled around the puling infant. At last an aged practitioner took the child's napkin, extracted it with water, and applied the guaiacum test. The test was positive and scurvy stood revealed. Modern medicine stands in little danger of forgetting that the body is the garment of the soul (or "ego" if preferred); an eye to the garments of the body may help occasionally.



Shell of (?) bed-bug. Ovum of Ascaris.

A DOUBLE ACROSTIC.

The following double acrostic appeared in the *Observer* of Oct. 14th. Its quotation here gives away the "uprights," but presumably the time for sending in the solution has expired.

A Paper and its Founder
A hundred years ago:
No reading could be sounder
For any medico.

1. No exit this: but there's no doubt
It is a way of getting out.
2. Although she downward glances cast,
Undoubtedly the girl was fast.
3. A friend in need I'm often found
When you are on your daily round.
4. 'Tis pink or red; but if it lack
Its heart, you can't deny it's black.
5. Upright judges by the dozen
Wear the coat of the weasel's cousin.
6. "His diet was of wheaten bread,
And milk and oats and straw,
Thistles, or lettuces instead,
With sand to scour his maw."

---

THE FIRST

Victor Horsley Memorial Lecture

ON THE

RELATIONS OF SURGERY AND PHYSIOLOGY.

Delivered before the Royal Society of Medicine on Oct. 25th, 1923,

y SIR EDWARD SHARPEY SCHAFER, F.R.S.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF EDINBURGH.

I HAVE felt it a peculiar honour to have been asked give the first Victor Horsley memorial lecture. I ad the less hesitation in acceding to the request that should do so because I am not only his oldest irviving scientific friend, but also his first fellow-orker. It is nearly half a century since he made is appearance as an eager, intelligent student in the d Physiological Laboratory at University College. iarpey had but recently retired from the teaching physiology, although his personal influence was ill felt. His place had been taken by Burdon-inderson, whose dominant idea was to make the ork of the subject as experimental as possible. ad anyone who has known Victor Horsley will adily understand with what keen interest this idea ould inspire him. There can indeed be no doubt was this training in experimental physiology which termined Horsley's future career both as a physiogist and as a scientific surgeon. And it is this uble career which may appropriately be chosen as example of the mutually beneficial influence of rgery and physiology.

I had almost been tempted by our long and intiate friendship, which began so auspiciously at iiversity College in 1875 and lasted until the day his death in Mesopotamia in 1916, to dwell, on is the first opportunity of commemorating his reer, upon the personal traits which were so striking feature of Horsley's character—his enthusiasm, his e of truth and hatred of hypocrisy, his energetic iving for everything he judged to be right and lexible antagonism to everything he thought wrong. it has not all that been done, far better than I or yone else could hope to do it, in the history which Stephen Paget has set forth, in that inimitable le which characterises all his writings? It is tunate that the life of Victor Horsley was ensted to such a biographer, nor was the biographer fortunate in having such a subject! How endidly he has taken advantage of his opportunity all of us know.

TERDEPENDENCE OF SURGERY AND PHYSIOLOGY.

have chosen the "Relations of Physiology and gery" as the text upon which to base the remarks ave to make to-day. It is my object to show that se subjects are mutually dependent: that physioy must call in the aid of surgery to solve many its most intricate problems, and that surgery not make any real advance unless it proceeds d-in-hand with physiology. It was not Horsley self who established this principle, but he haped upon the time when it was beginning to be lent. Only a few years before it might have admitted that there was a certain amount of rdependence between medicine and physiology, no one would have thought of connecting surgery anything but anatomy. That experiments on nals were necessary in order to elucidate the tions of the body had indeed been conceded. It recognised from Harvey onwards—yes, and long re Harvey—that no true advance could be made hysiology without such experiments. The operas involved in them have somewhat unfortunately ived the designation of "vivisection," and this has caused many who are ignorant of their nature to regard them as of an entirely different character from surgical operations in the human subject—although they are conducted in exactly the same manner as in man, with the same precautions to prevent unnecessary pain and with every effort to avoid unsatisfactory complications which might result from wound-infection and the like. But many of the older surgeons refused to believe that an operation on the lower animals could be utilised to obtain information which would be useful to them in the performance of similar operations in man, nor should I be surprised to hear that there are some who still hold this view. It is fortunate for the world that Victor Horsley was not one of these.

As I have remarked, he happened upon a time when the importance of animal experimentation as a guide to surgery was beginning to be recognised. There were two directions in which this tendency was particularly apparent. One of these involved the investigation of the functions of the brain, the other of what we now term endocrine organs—the uses of which were then for the most part obscure. And it was just these two subjects which attracted the attention of the physiologically trained but hitherto unknown young surgeon whose work was to throw so much light upon these dark places of the organism, places which hardly anyone had hitherto ventured to approach. It is on this account that I propose to deal first with these particular aspects of the question of the relations of surgery and physiology. I will begin with the subject of the functions of the brain and its related subject, cranial surgery.

CRANIAL SURGERY AND THE FUNCTIONS OF THE BRAIN.

Not very long before the entry of Victor Horsley to University College as a medical student, a young Scottish physician named David Ferrier published an elaborate series of researches on the results of electric stimulation of the cerebral cortex in animals. Some of these were confirmatory of experiments performed on the dog and cat by Fritsch and Hitzig, although the method of stimulation employed by Ferrier was a vast improvement on that used by the German observers. But what rendered Ferrier's results really important was the fact that he extended these researches to the brains of monkeys, which are entirely different in the conformation of the cerebral cortex from the brains of the dog and cat, but present a remarkable resemblance to the brain of the highest member of the order Primates, man. It is scarcely necessary to say that the brilliant experiments of Ferrier aroused universal interest. I shall myself never forget the impression made upon me by one such experiment which Ferrier showed to Burdon-Sanderson and the rest of us who were working in his laboratory. The confident way in which he could predict what would be the movement resulting from touching this or that portion of the cortex with the electrodes was calculated to arouse our wonder and admiration; and the demonstration always provokes the same feelings in every audience of students when the experiment is repeated before them. It was these experiments—supplemented as they have since been by those of Horsley and Beevor on the brain of the orang, and by the yet more recent and accurate results obtained by Sherrington and Grünbaum upon the orang, chimpanzee and gorilla—which have enabled the surgeon to locate the seat of an injury and tumour in the human brain, and to remove the tumour or to deal with the source of injury with advantage to the patient.

In all researches in experimental physiology, there are two chief methods employed to elucidate the functions of an organ. One is the artificial stimulation of the organ, causing it to pass into a condition of activity, the effect of such activity being duly noted. The other is the production of an injury in the organ, or its complete removal, the effect, if any, which results from such injury or removal being observed. With regard to the functions of the brain, this last aspect of the subject had by no means been neglected by antecedent workers, but discrepant results had been obtained. Indeed, up to the time of which I am speaking—i.e., the epoch of Fritsch and Hitzig and of Ferrier—physiologists were disposed to agree with Flourens that the whole cortex acts as one undivided organ and that the several parts of the body are not individually represented in it; in other words, that there is no such thing as localisation of functions in the cerebrum. One acute clinical observer, Hughlings Jackson, had, it is true, pointed out that the phenomena of traumatic epilepsy seem undoubtedly to indicate the existence of some kind of localisation in the cortex; since the "march" of the movements which result from the excitation producing the epileptic fit is different according to the seat of injury. But such a complete localisation as we now know to exist was unsuspected, and it was largely on this account that so much interest was aroused by the excitation experiments of Ferrier.

But if excitation of a particular area of the cerebral cortex provokes certain movements, it does not follow that we are to regard that area as representing a nerve centre for governing or producing those movements unless removal of the area is followed by paralysis of the movements. We may leave out of present consideration whether the so-called centre is automatic—i.e., works spontaneously—or whether it only represents the point of arrival of sensory impulses and the point of departure of the corresponding impulses to motor centres in the lower part of the central nervous system—i.e., whether it is a reflex centre. For this question, which was warmly debated at one time, may now be considered to be definitely settled in favour of the second hypothesis. In either case the final result of excitation and of ablation will be in the first case production of definite movements, in the second the inability to perform them.

At the period I am speaking of, many of the facts had been established, but the explanation was a matter of controversy. There were, moreover, still certain parts of the hemisphere which Ferrier had not explored, or which in his hands had yielded negative replies. And the results of the extirpations which he had performed in conjunction with his colleague Gerald Yeo, then professor of physiology in King's College, were not altogether satisfactory, nor did they agree in certain particulars with the work of others, especially that of Herman Munk, of Berlin, who was working on much the same lines both in the dog and monkey.

RESULTS OF REMOVAL OF DEFINITE AREAS OF THE CORTEX.

This, then, was a problem still needing elucidation, and when in 1883 I succeeded Burdon-Sanderson in the Chair of Physiology at University College, it was one of the first investigations at which I resolved to work; especially with the view of determining more exactly the results of removal of definite areas of the cortex. Now Ferrier and Yeo's work—I am referring only to their earlier work, the later was accomplished under different conditions—had been done by pre-Listerian methods, and I felt convinced that this might be the source of some of the discrepancies exhibited, as compared with the results of Munk and others. My own surgical training was unfortunately pre-Listerian owing to the slow progress which was made in London in the adoption of Lister's methods, and the active opposition with which they were met by many of the leading London surgeons. I therefore recognised the necessity of securing as a collaborator a young and skilful surgeon thoroughly imbued with Listerian ideas, and enthusiastically interested in physiology. You may easily understand that I had no difficulty in making my selection, for Victor Horsley fulfilled all these conditions, and we were already on terms of personal intimacy. Gleefully did he accept the proposition that we should carry out this work together, and many were the hours which we devoted to it.

In every case the first part of an experiment consisted in exploring by induction currents after the manner of Ferrier the particular area we desired to investigate, and the second part in removing the explored area, re-covering the brain, and sewing up the wound. In these operations we made use of every Listerian practice, including, to our woeful discomfort, the recently introduced carbolic spray—a source of endless objurgations!

To these operations Horsley brought a remarkable amount of surgical skill. Our quadrumanous patients were kept under the best possible conditions, and in most cases made speedy recoveries. It is not saying too much if I add that Horsley obtained from these experiments a surgical experience of a unique kind. This experience he was presently—in his capacity of surgeon to the great hospital in Queen-square—to apply to the alleviation of human suffering in a domain which even the boldest surgeons had not ventured seriously to attack.

There is no better illustration of the mutual benefit which results when surgery and physiology go hand in hand than the history of our early efforts in this field of investigation. The benefit to Horsley I have pointed out. And for myself, I acknowledge with gratitude the debt I owe to my colleague for the opportunity I was afforded of learning the application of Listerian surgery to animal experimentation, a lesson the benefit of which I am more than ever conscious of after nearly 40 years' experience, much as things have changed both in physiology and in surgery since that far-off but never-to-be-forgotten time.

Our partnership was a fruitful one. We were able to extend Ferrier's observations in the monkey's brain to parts which he had not explored, although in this particular he had not left much for future investigation. But the young worker may take it from me who have grown old and experienced in scientific investigation, that if he wishes to discover new thing he will do well to repeat with the aid of moder methods any experiment which has been long accepted as affording the last and most incontrovertible word on the subject. Almost certainly he will find som point which has been overlooked by the origina investigator, and needless to say by those who hav merely aimed at getting the same results. And almost certainly the exception will prove—i.e test—the rule, and he may easily find that which ha been looked upon from time immemorial as scientifi gospel is badly in need of re-editing. In my experienc nothing is so fertile in discovery as going carefull with one's eyes open, and with the aid of new method along a well-worn track. I say with one's eye open—for if they are shut to everything but what on expects to see many a discovery will be overlooked.

It is not my purpose to give an account of ou work on the brain—work which, begun together, wa eventually by force of circumstances carried o independently or in conjunction with other worker One word, however, I would say about a trait in m colleague which, although in no way unfavourab to his character, rendered the actual conduct of ou joint investigation somewhat laborious. He was to energetic. He would think nothing of performin several operations at a sitting, and acquired so muc skill at them that they occupied a relatively sma amount of time. But the operation was one thin the study of the symptoms quite another. Now takes a long time to make a thorough investigati of symptoms in the human subject—although in th case the subject himself can give much assistanc But when it comes to making the same kind investigation in animals, and especially in monkey which are often wild, and the attention of which it always difficult to fix, an unconscionable amount time has to be devoted every day to each case. It happened that just about this time Horsley w leading an extremely busy life. He was surgic registrar at University College Hospital—a positi involving a huge amount of clerical work—and lat assistant surgeon there; professor superintendent the Brown Animal Sanatory Institution; assista professor of pathology in University College; had considerable if not very remunerative private pra tice; and last but not least, was engaged to married. The result of all this was that most of the observations on the operated animals had to be made by his colleague, and when there were several to be examined the amount of time that these occupied every day rendered the duty severe. All the clinical notes thus taken day by day had to be collated and eventually boiled down—a process which involved many prolonged conjoint sessions. Upon the results of this collaboration I need not dwell. Are they not written in the Chronicles of the Royal Society and decently buried in the Philosophical Transactions? May they rest there in peace!

The experience which Horsley had gained in these experiments—commenced in the laboratory at University College, and continued at the Brown Institution—was invaluable to him in dealing with cranial surgery in man, and when the position of surgeon to the Hospital for Nervous Diseases in Queen-square fell vacant Horsley received the appointment. He lost no time in applying the knowledge he had acquired in the laboratory to the operating theatre in the hospital. Paget gives an interesting and humorous account of the first operation he performed there for a cranial tumour. It was upon a Scotsman, was in every way successful, and was witnessed by a distinguished company which included Hughlings Jackson and Ferrier. It was, of course, followed by many others, and these were often attended by eminent foreign surgeons, for Horsley's reputation as a cranial surgeon soon became widespread. The facility with which he used either hand contributed not a little to the dexterity of his operations, and he never under any circumstances lost the sang-froid which is essential to a surgeon.

THE THYRO-PARATHYROID APPARATUS.

Although by the work which Horsley had done upon the brains of monkeys and apes, he had become one of the most skilful and scientific operators upon that part of human anatomy, he was much too all-round a man to confine himself to a single object, and we must next follow his career in another subject —that, namely, dealing with the functions of the thyroid gland—to which he brought equally keen enthusiasm for physiological investigation, and skill n surgical procedure. Like that upon the functions of the brain this also has an interesting preliminary history.

The year before Victor Horsley was born, Moritz Schiff, of Geneva, one of the most active physiologists of the middle of the last century, had published the esults of observations he had made upon animals, he thyroids of which he had extirpated. But at that ime neither physiologists nor medical men were prepared to take much interest in the thyroid, nor ndeed in any of the so-called ductless glands, which now, under another name, occupy so prominent a position both in physiology and in clinical medicine. Schiff's work, therefore, which was not without nterest and importance, passed unnoticed, and the matter was allowed to rest for many years. But ust about the time that Horsley was starting his urgical career, the subject of the thyroid and its unctions had come into prominence on account of he fact that it was becoming the practice amongst urgeons in Switzerland—in which country tumours f the thyroid are common—to remove such tumours ntirely when they were inconveniently large. In uch cases of complete removal serious symptoms ften resulted—symptoms which closely resembled hose which had been described some ten years reviously by Sir William Gull, as a cretinoid condition of adult life, and were later shown by Ord to be ssociated with absence or atrophy of the thyroid; rd applied the term myxœdema to the syndrome. he symptoms resulting from thyroid removal were ecognised by J. and A. Reverdin as resembling those myxœdema, and they gave to them the name perative myxœdema. Th. Kocher, who described hem at about the same time, spoke of the condition s *cachexia strumipriva* or *thyreopriva*, the name by which it is now generally known, although the term operative myxœdema best describes its cause and symptoms. These observations of the Swiss surgeons were published in 1883, and led immediately to a great revival of interest in the thyroid both amongst physicians and clinicians. Schiff himself repeated and extended his old experiments, and many other physiologists took up the subject, interest in which is indeed by no means exhausted even at the present day.

How Victor Horsley came to start experiments upon the thyroid is narrated by Paget:—

> "On Nov. 23rd, 1883, at a meeting of the Clinical Society of London, there was a discussion over a case of myxœdema shown by Dr. Drewitt; and Felix Semon called attention to Kocher's observations and said positively that cretinism, myxœdema, and cachexia strumipriva were closely allied conditions, having in common either absence or probably complete degeneration of the thyroid gland; and that they could hardly be attributed to any other cause. On Dec. 14th, the Clinical Society appointed a committee to investigate the whole subject. Ord was chairman, Hadden was honorary secretary, and Horsley was a member of the committee. It was of necessity that the investigation should include an experimental study of the healthy gland in healthy animals; . . . . and recognising 'the hitherto undreamt of importance of the thyroid gland' they asked Horsley to study it by the experimental method. They needed a physiologist and a surgeon, and they had them in him."

Horsley started this investigation in my laboratory at University College, working at first with Rickman Godlee, who was also a member of the committee. They made several experiments together upon monkeys; we had a room specially prepared and warmed for keeping these animals. But very soon the work was transferred to the Wandsworth-road, Horsley being now professor superintendent of the Brown Institution there, and he found it inconvenient to carry on work in both places. So he continued the investigation alone, and dealt with the results in the lectures which he was expected to give annually at the University of London, the first of these being published in the *British Medical Journal* in January, 1885, and the next in *The Lancet* in 1886. It is somewhat singular that with the exception of two short notes communicated to the Royal Society, he never took the trouble to send the results of these experiments upon the thyroid to any scientific periodical, although they were mentioned in his annual reports to the committee of the Brown Institution, and ultimately in the report of the Committee on Myxœdema, published in 1888. The reason for this silence on the part of an investigator like Horsley, who never in any other subject had the least hesitation in giving his results to the world whenever they were sufficiently definite, was, I imagine, because of a certain indefiniteness and variability in the effects obtained from removal of the gland. For some animals were simply rendered apathetic, with slow movements, a low body temperature, and a general deficiency in vitality; others showed acute nervous symptoms, with muscular tremors; which might pass into fits of greater or less violence, and terminate in death. Horsley himself seems to have thought that these were stages of the same condition. But we now know that the two kinds of symptoms were due to entirely different causes; in the one case the thyroid alone had been removed, and in the other the removal had included the parathyroids. Unfortunately, at the date of these experiments, the parathyroids, although they had been seen and described some years earlier, had not been recognised as organs having a specific function entirely different from that of the thyroid. It was only some years later (1891) that Ernest Gley, the eminent professor of physiology in the Collège de France, discovered this function, and showed that the symptoms of nerve excitation are entirely due to the removal of the parathyroids, and are not seen when these, or some of them, are left intact in removing the thyroid. On the other hand, removal of the thyroid alone without the parathyroids produces all the symptoms of cretinism and cachexia strumipriva.

The fact that when dealing with young animals the parathyroids, unless looked for, and they were at that time unknown, were more likely to be removed along with the thyroid (as age advances, some of them move farther away from the thyroid) accounts for the circumstance that Horsley found most of his young animals died in a few days with violent nervous symptoms. In consequence of this he missed the very important point that the thyroid exerts a remarkable influence on growth and nutrition, including the nutrition of nerve cells, which is indeed now established as one of its principal functions. But we cannot blame him for missing this point, since our knowledge of the thyro-parathyroid apparatus was not sufficiently advanced at the time.

The Pituitary Body.

There is another important endocrine organ to which Horsley devoted a good deal of attention—viz., the pituitary body. He was, I believe, the first to endeavour to determine the effect of removal of this organ, for about 1886 he made one or two attempts to reach and destroy it through the pharynx and base of the skull. The conclusion he arrived at was that it is an organ which is not essential to life. Many years later he repeated these experiments and apparently saw no reason to alter his opinion, although in the meantime a number of other investigators who adopted other means of reaching the gland had come to an opposite conclusion. There is now no doubt that, in most adult animals at least, the loss of the pituitary body or even of its anterior lobe alone is incompatible with life, and had Horsley proceeded to attack the gland by the same (lateral) route as has been employed by most other investigators, a route in which every step of the operation is visible and perfect asepsis can be ensured, he would, I am sure, have obtained the same results. His original method offers many difficulties from the liability to hæmorrhage and sepsis, and from the impossibility of seeing what one is removing when working at the bottom of a deep and narrow hole. Horsley was inclined to regard the results obtained by those who operated by the lateral method as due to interference with the brain; but this could not be so, for exactly the same operation can be performed for exposure of the pituitary, but if it is left untouched no adverse symptoms follow. Moreover, one of my assistants, Mr. Norman Dott, himself a skilful surgeon, has recently devised a method of destroying the gland completely in the cat, by a process of electrolysis, without any exposure or any injury to the brain. The sella turcica is reached by passing a fine trocar, enclosing a carefully guarded needle, along the outer margin of the orbit, and through the sphenoidal fissure. This needle conveys the necessary current and the whole operation occupies only a minute or two. By careful adjustment of the position of the electrolysis needle it is possible to destroy either the anterior or posterior portion of the pituitary. If the anterior part is destroyed, the animal will inevitably die within two or three days, a result precisely similar to that obtained by Paulesco, Harvey Cushing, and others, when operating on adult dogs by the lateral method.[1]

Although Horsley had occasion to perform on the human subject a certain number of operations for removal of tumours of the pituitary, his physiological experience in connexion with this organ had not the same influence in determining the corresponding surgical proceedings in man as had the experiments upon the brain. This was partly owing to the fact that tumours of the pituitary are rare, and the methods for getting at the pituitary in the human subject are different from those employed for animals. Moreover, such tumours are often very slow growing, and are not attended with immediate risk of life; whereas complete removal of the gland is dangerous if not fatal. And with regard to tumours of the thyroid, they can often be successfully treated without operation, and only occasionally pass from the hands of the physician into those of the surgeon. But I have, I hope, said enough about the physiological and surgical work of Horsley to illustrate the subject of this address, the close relationship that should exist between physiology and surgery. Horsley himself laid particular stress upon this relationship. Mr. Paget tells us that when in January, 1911, the first Lannelongue prize—which was to be awarded once in five years to the surgeon who in the previous ten years shall have done most for the advancement of surgery—was presented to him:

> "He spoke a few words of thanks . . . . and said that his own country which had long been under the influence of John Hunter, had later come under the influence of Claude Bernard, who had joined together physiology and surgery. 'That is what I have striven to realise. Unfortunately, if surgical science advances with fair rapidity, its practice progresses slowly. That is because we are held in bondage by traditions from which we have difficulty in freeing ourselves.'"

Clearly he meant by this the supposed dependence of surgery on anatomy, when he himself clearly saw that it is physiology which it must in future depend upon, or only so far on anatomy as mechanical considerations may render necessary.

Lister and Physiology.

I next propose to give you an illustration of the mutual importance of surgery and physiology from the career of the most eminent surgeon of our generation, Joseph Lister. Lister was essentially and fundamentally a physiologist. He was easily the most distinguished pupil of William Sharpey, and William Sharpey was unrivalled as a teacher of physiology This is the more strange, since Sharpey himself did little or no original work in the subject. Nevertheless no one gave greater encouragement to his pupils to conduct physiological inquiries or more sympathy in their researches than did he. The failure on his part to carry out physiological investigations was due to his training. This was wholly anatomical. When he went to study in Germany it was Rudolphi's dissecting room he frequented, not Johannes Müller's lecture room and laboratory. Had he attached himself to the last-named, he would have consorted with all the great German physiological workers of the middle of the last century—Helmholtz, du Bois-Reymond Ludwig, Brücke; or had he gone to Magendie in Paris instead of to the anatomical and surgical schools there, he would have consorted with Claude Bernard and would have become the outstanding physiologica investigator in Great Britain and have occupied the place in London which Bernard occupied in Paris. Bu the tendency of the Edinburgh School in his day was wholly in the direction of anatomy, doubtless owing to the fact that the anatomical chair in Edinburgh had been occupied by a succession of pure anatomists —a tradition which has been handed down to the present day; whereas, although there existed a Chair of Physiology even prior to that of Anatomy rightly known as the "Institutes of Medicine," it was never held by a physiologist until the appointment of Rutherford in 1884, of whom I am myself the unworthy successor. Whatever may be the case now—and we have illustrious examples to the contrary—anatomy in those days exercised an influence upon its devotees which was not favourable to active research and least of all to experimental work. It must further be remembered that Sharpey was actually a lecturer on anatomy in the extramura school of Edinburgh when he was invited to occupy the chair of general anatomy and physiology at University College. Up to that time he had not taught physiology, nor had he received any training in it; although he had interested himself in certain physiological problems, especially those connected with the growth of bone and the action of cilia. It was too late for him to undergo a fresh course o training, and he was busy with his new duties. He had, therefore, to get up his physiology as best he could. The Council of University College would have done well if they had given him a free year to study physiology in France or Germany, but in those days here seemed to be no idea that anything of the kind vas necessary; the governing bodies of universities arely do the right thing in these matters! So Sharpey iad to be content to teach a subject in which he was nly self-trained. The more credit to him that he ecame so successful. For it is certainly due to his eaching, both directly and through his pupils, that he physiology of the latter part of the nineteenth entury became preponderatingly an English science. trust we still remain in the forefront, but we must dmit that other nationalities have during the last ive and twenty years made notable advances and re able to challenge any predominance we may ave had.

---

[1] The details of this method will be published in the next number of the Quarterly Journal of Experimental Physiology.

If I have been led away by the reverence I have for is memory to speak at greater length of Sharpey han I had intended, I feel justified in doing so ecause of his intimate connexion with Lister. Lister, ong before he was known as a surgeon, was an xperimental physiologist, and he continued to be ne throughout his career. He had had no opporunity of being trained in experimental work, but e was a born experimentalist and trained himself. Whether he would have done better to have worked vith Claude Bernard in Paris or with Carl Ludwig n Leipzig must be a matter of opinion, but his selfraining had at any rate the advantage of developing is originality. His first scientific investigations vere made with the aid of the microscope—an nstrument with which he had, through his father, he discoverer of the achromatic lens, been familiar rom his earliest days. He was one of the first to emonstrate the existence of a dilatator pupillæ in he iris and to show that, like the sphincter pupillæ hich was already known, the dilatator is composed f plain muscle cells. Many later observers, less kilful or less accurate than Lister, have denied the xistence of this muscle, but his work has been indicated and confirmed by the most modern ethods both of physiology and histology. Shortly fter this he published observations on the arrectores ilorum which confirmed those of Koelliker, and are specially remarkable because he used a new and ow universally employed method—that of microcopic sections—for the investigation. Doubtless the tudent of the present day, familiar with paraffinbaked tissues and mechanical microtomes, would espise the rough mode of preparation used by ister. To use his own words: "A portion of shaved calp being placed between two thin slips of deal, a iece of string is tied round them so as to exercise a ight degree of compression; the preparation is ow laid aside for about 24 hours, when it is found have dried to an almost horny condition. It then dheres firmly by its lower surface to one of the slips, nd thus it can be held securely, while extremely hin and equable sections are cut with great facility any plane that may be desired. These sections, hen moistened with a drop of water and treated ith acetic acid, are as well suited for the investigaon of the muscular tissue as if they had not been ried."[2]

The existence of such cells in plain muscle had been enied by Ellis in a paper published in the Philophical Transactions, although Koelliker had proaced abundant evidence to the contrary. And very student can now easily demonstrate them. ut in those days it was not so easy, and the fact at Lister undertook a difficult investigation and cceeded so admirably in obtaining a definite result aced him at once in the first rank of physiological stologists.[3] It is true these observations were not themselves purely physiological, but their interest entirely so, and had this not been the case it is oubtful if Lister would have spent so much time and trouble over them. It is interesting to remark that both investigations were inspired by the work of Koelliker, who was the predominant histologist of his time, but whose training and early work were physiological. Koelliker was an intimate friend of Sharpey, and it was through Sharpey that Lister made his acquaintance. Incidentally I may be allowed perhaps to mention that it was through Sharpey that I myself made the acquaintance and experienced the constant and kindly encouragement of both Koelliker and Lister.

The distinctively physiological bias of Lister's mind was soon to be evidenced (1) by his work on absorption from the intestine and on the flow of chyle in the lacteals, and (2) by his researches on the vascular changes accompanying inflammation. The first of these researches was made in 1853, while he was still in London, and shortly after he had graduated. Their chief object was to ascertain whether solid particles mixed with the food can be absorbed by the lacteals. He observed these vessels in the mesentery of the mouse, and the conclusion he came to was that no such absorption occurs—a conclusion which has never been modified since. The experiments on inflammation were made, or at any rate completed, after he had been definitely established as a young surgeon in Edinburgh: a place he visited on Sharpey's recommendation in 1853, with the intention of spending a month there; but he became Symes's assistant and eventually his son-in-law, and the month extended to seven years!

Having become conscious of the ignorance of surgeons regarding the earlier stages of inflammation, he set to work to investigate these on physiological lines. For this purpose he made use chiefly of the frog's web, but employed also for confirmatory evidence the vessels in the bat's wing—an object he had learned the study of under one of his most distinguished teachers in University College, also a physiologically-minded surgeon, Wharton Jones, the discoverer of the amœboid movement of leucocytes. As his biographer truly remarks, his work on inflammation "impresses the reader by the beauty and simplicity of the experiments described, the originality of the thoughts, and the soundness of the reasoning. . . . The paper was well received at home and on the Continent, and its conclusions have with scarcely an exception stood the test of time."[4] In the same year Lister published also two other papers in the Philosophical Transactions—viz., "An Inquiry regarding the Parts of the Nervous System which regulate the Contraction of the Arteries," and on the "Cutaneous Pigmentary System of the Frog." Both of these are of great physiological interest and contain new and important observations. It is, however, not to be wondered at that his predominant work, which has revolutionised surgery, should have overshadowed his earlier physiological observations, a fact which Lister himself recognised and regretted. I am not sure in my own mind that he was not prouder of his physiological work than of his contributions to surgery.

Blood Coagulation.

His most important contribution to physiology was when he was very fully occupied with surgical work and teaching. It was upon a subject which must always possess a peculiar interest for the surgeon—the cause of blood coagulation. I know of no better or more precise piece of physiological work than this. All kinds of theories were then extant on this subject; there are a good many still! Dr. Benjamin Richardson, who had found that the addition of ammonia to blood would prevent its coagulation, thought that this furnished sufficient evidence to support the notion that the reason blood coagulates when drawn is

---

Quoted from "Lord Lister," by Sir Rickman Godlee, 1917.

[3] The earlier papers on this subject were published in the arterly Journal of Microscopical Science, for 1853; the fuller vestigation in the Transactions of the Royal Society of linburgh for 1857. They are all to be found in vol. i. of his Collected Papers," 1909.

[4] This paper was read before the Royal Society in 1857 and published in the Philosophical Transactions for 1858. The actual mode of causation of the vascular changes which Lister was the first to describe was not explained until many years later, the explanation being furnished by the experiments of Dr. Ninian Bruce, working with Professor Hans Meyer, and published in the Quarterly Journal of Experimental Physiology, vol. vi., 1913.

because exposure to air allows the escape of ammonia. And although the researches of Alexander Schmidt had shown, what modern investigations have confirmed, that coagulation is the result of a chemical reaction between substances dissolved in the blood, the reason why this reaction does not occur in the living vessels was completely obscure; the theory which was most favoured being that of Brücke, which explained the phenomenon by supposing that the living wall of the vessel exercises a restraining influence upon the blood in contact with it—which is evidently not an explanation at all. Lister devised a simple experiment which at once upset both theories, and indicated the real cause of blood coagulation—viz., the contact of blood with foreign matter or with injured or dead tissues. He showed that blood can be kept fluid in a segment of a large (surviving) vessel exposed freely to the air, and could even be poured from one such segment to another so as to allow free escape of any ammonia which might be (but isn't) present; moreover, whilst passing through the air the blood would, of course, be removed from contact with the wall of the living blood-vessel. Nevertheless, such blood remained fluid unless the inner coat of the vessel were injured or unless the blood were allowed to come in contact even within the vessel with a foreign body. Lister showed that it is the presence of the injured tissue or foreign body that determines the chemical reactions which produce the coagulum, and not the presence of the living tissues which prevents such reaction. This fundamental fact was settled for all time by the simple experiment of the so-called "living test-tubes" devised by him. The account of this and other experiments on the subject is to be found in the Proceedings of the Royal Society for 1863; it formed the subject of the Croonian lecture for that year.

Vivisection.

By this time Lister was in the full swing of professional work in Edinburgh, and was giving lectures on the principles and practice of surgery in the extramural school. The principles he taught were physiological, both normal and as applied to disease. He recognised that surgery, if it is to be considered a science at all, must be founded upon and can only make progress by the aid of experiments. His great discovery was so founded. His experiments were made with test-tubes, with animals, with patients. But he would never venture to perform a serious experiment upon man without having ascertained by animal experimentation that it was likely to prove successful and was therefore justifiable. On the subject of vivisection his trumpet gives no uncertain sound. When requested by no less a personage than Queen Victoria to make some public declaration against vivisection, he replies as follows to her private secretary:—

> "I should deeply regret that I cannot see my way to complying with this request, were I not persuaded that my doing so would not promote the real good of the community, which I know to be Her Majesty's only object in the matter. And I feel bound to endeavour to express shortly the reasons for my opinion. With this object I can hardly do better than begin by saying that I have myself often performed experiments upon the lower animals, and that, if I have been privileged in my professional career to do anything for the good of my fellow men, more is to be attributed to these experiments than to any other work in which I have engaged. When they were performed without chloroform, as has not infrequently been the case, they have been done at a very great sacrifice of my own feelings; but the greatness of the object in view has appeared to me to over-ride such considerations. . . . It is sometimes said that, although such experiments may be needful and right for the purposes of discovery, they are not justifiable for the demonstration of truths already ascertained. It would, I believe, be very wrong to draw any such line of distinction. To take a single instance—to debar the student of medicine from having his eyes opened to the truth of the circulation by seeing the blood coursing through the vessels of the living web of the frog's foot, would be undoubtedly a mistake; for no amount of verbal teaching could do for him what a glance through the microscope at that sight at once effects."

And after explaining at considerable length the relatively painless nature of physiological experiments as compared with the cruelties which are inflicted every day for the sake of improving the quality or appearance of food, or even in sports such as fishing, shooting, and fox hunting, he points out that the sportsman is not commonly regarded as cruel because the inflicting of suffering on the hunted animal is not his main object (which is merely the gratification of himself and his friends) and continues:—

> "But surely those who regard this amusement as justifiable are strangely inconsistent if they brand with the epithet cruel the man who performs an experiment upon an animal at great sacrifice to his own feelings and with every care to render the pain as slight as is compatible with the high object in view."

In his evidence before the Royal Commission on Nov. 1st, 1875, he begins by stating that his first experiments upon animals had been made when he was altogether unknown as a person of any sort of reputation whatever:—

> "When I first took in hand to teach others, I felt that there were some points on which I desired more information than I could get satisfactorily from any book, and my first experiments were performed with the object of preparing myself for teaching, while I was not a person of recognised scientific attainments."

With regard to his early experiments upon blood he remarked that they "had the effect of giving me a kind of pathological information, without which I believe I could not by any possibility have made my way in the subject of antiseptics; and that subject, I believe, is becoming recognised as one of considerable practical importance. I have often felt that without the basis which I derived from experiments on the lower animals, I should never have been able to thread my way through the very perplexing and apparently contradictory facts which I met with in the first instance," also that throughout his whole career after that time he had found experimentation on living animals necessary, and that through the medium of that experimentation originally commenced with other aims he was gradually led "to the development of that method of treatment which is now known as the antiseptic system." Further, with regard to his work on catgut ligatures he definitely states that if he had not made experiments in the first instance on animals he would have had to perform them on man; there was no other alternative.

Physiology the Basis of both Medicine and Surgery.

Engrossed as he was with surgery, Lister never ceased to be a physiologist, and to the end of his days was deeply interested in all forms of experimental work. He was scientific to the core. He admitted, as we have seen, that experimental work was the basis of all his researches in antiseptics, and his work in this as in other directions was characterised by meticulous accuracy, a character which is essential for all scientific investigations. First the facts were ascertained by observation and experiment; then marshalled and collated with observations made by others; the deductions checked by yet other experiments; nothing was left to mere supposition. In this way he arrived at the great generalisation which at once transformed surgery from a mere art which might be practised by any ignorant person into a real science which could only be properly advanced by those who adopt scientific methods. Given an adequate knowledge of anatomy—which is essential both to the physician and to the surgeon—the basis of training in both the branches of what is popularly known as the "healing art" must be physiology. Lister would never have arrived at the position he occupies in the history of surgery if he had not been first a physiologist. Doubtless he was fortunate in his opportunity. He came at the right time, just when Pasteur was engaged in the brilliant researches which indicated the essentially parasitic nature of disease. How eagerly Lister seized hold of that opportunity we have heard from his biographer, and his own tribute to the assistance he obtained from the researches of Pasteur is unstinted; although he had begun his own experiments before he had heard of Pasteur's. I do not know of any surgical con temporary of his who could have taken advantage of the opportunity thus offered; at any rate it is certain none of them did so. They all had anatomy at their fingers' ends, but this was the only science which it was then expected they should know, and it did not lead their surgery far along the path of progress.

It is an old tradition that anatomy is the exclusive basis of surgery, but I am happy to think it is every day becoming more of a tradition and less of a practice. Many modern surgeons both in this and in other countries are physiologists as well as surgeons. Physiology has given scientific support to their surgery, and has been in turn materially assisted by it. It would be invidious for me to mention the names of living individuals and in an assembly like this it is not necessary; they are known to most of you. They admit that surgery is based upon experiment; in other words, upon physiology, and that there is no possibility of its advancing in any other way. Like every other science, surgery without experiment must stand still, and no surgeon has any right to experiment upon the human subject if the lower animals are available for the purpose. That those who are learning operative surgery are debarred by Act of Parliament from practising on animals, although permitted to make any experiments they think fit upon human patients, is an incredible piece of folly. Ours is the only country in the world in which so heinous a measure could have been passed into law; the only nation where misplaced sentiment is allowed to displace reasoning, and where the necessities of humanity are subordinated to those of the brute creation. I wonder does the British public fully understand that by the present law no student is permitted to perform any experiment upon an animal with the object of enabling him to do the same operation upon man, and to acquire the necessary skill to do it without danger to his patients. Which of you, I may ask, would like to be the first patient to be operated on even for the so simple operation as the extraction of the crystalline lens? Yet the skill of the operator *must* be acquired by experience, and therefore men, women, and children take the place of dogs, cats, and rabbits. As Sir Rickman Godlee pertinently remarks—

> "The strangest anomaly, as it must appear to our less sanctimonious brethren in the rest of the civilised world, is that our law, while it forbids the granting of a special license to a distinguished doctor to experiment on a chloroformed frog in his own study in pursuit of science, allows anyone who can afford it to hunt a stag to death, or set two greyhounds to course a hare and wager money on the result."

Truly we are a nation of Pecksniffs!

TEAM-WORK.

While it is the case that the progress of surgery must depend upon physiology, it is equally true that the progress of physiology depends upon surgery. Without an adequate knowledge of surgery many experiments which are necessary for the advancement of physiology could not be attempted. I have already given you instances of this, but I will adduce another from the experiments on depancreatised animals which are at present in progress, accounts of which are filling not only the pages of the medical and physiological journals, but even the columns of the daily press. Such experiments can hardly be conducted by one individual. It is not everybody who is endowed, as Lord Lister and Sir Victor Horsley in great measure were, with the requisite knowledge and skill in both subjects to work single-handed. At the present time the importance of team-work, suitably directed, is fully recognised, and this is largely why our knowledge regarding "insulin" has made such rapid advances. Surely such a combination of physicians, surgeons, physiologists, biochemists, pathologists has never before been assembled to conduct any investigation as those who have been working in Toronto. In every combined physiological investigation on animals, one of the team at any rate should be a surgeon, and I can conceive of no more advantageous training for a young surgeon than that which he will obtain by taking part in such an investigation. Examples of the mutual value of coöperation between the surgeon and the physiologist could easily be multiplied, but I hope that those I have put before you are sufficient and may have some influence in promoting that close intercourse between surgery and physiology which is essential for the progress of both branches of science.

I have often wondered what difference it would have made to my own life if Joseph Lister had been elected to the chair of surgery in University College in 1866 instead of John Marshall. It is easily the worst mistake that the Council of the College ever made. The echo of the election was remaining when I joined the College in the winter of 1866 as a very young student. I came to know Marshall very well. He was a good friend to me, and I had a great respect and liking for him. But he was the most uninspiring teacher that I ever sat under. His systematic lectures were desperately dull, and being given late in the afternoon with a monotonous, musical utterance, most of his audience were soon fast asleep; I was one of the sleepers! Nor was his clinical teaching any better; his operating was slow and the reverse of brilliant. Whether he ever fully embraced Listerian methods—at the time I joined they were unknown outside Glasgow—I do not certainly know, but I much doubt if he did so. He was not a physiologist, although he published a text-book of physiology, largely founded on his notes of Sharpey's lectures; I do not think it went through more than one edition. Lister's biographer speaks of Marshall as scientific and a good teacher, but these are terms which I cannot endorse. He had a charming personality, and as he was already on the staff of the hospital he obtained the chair in preference to Lister, who had been many years away from the institution and was unknown both personally and through his work to most of the staff. John Marshall became a Fellow of the Royal Society and President of the Royal College of Surgeons. There is an admirable bust of him at Lincoln's Inn Fields. But Lister's name will still be famous when Marshall's is forgotten.

It has always been a source of regret to me—as it must be to all alumni of University College—that Lister's work was not carried out at his old school. But the fates ordained otherwise, and to Glasgow and Edinburgh must be conceded the credit of nursing the new surgery into vigorous existence. I believe it would have made a great difference in the rapidity of the spread of the new doctrines if they had emanated from London sooner, and Lister no doubt thought so himself, as his subsequent migration to London showed. And the atmosphere of University College—if not of the Hospital—was distinctly scientific, and at any rate amongst his scientific colleagues there he would have received full encouragement. It was in 1866 that Lister applied for the appointment—less than a year after he had started his experiments on antiseptics in Glasgow. It was 16 years (1882) before Listerism came into general use in hospital surgical practice in London. The change occurred when Horsley was still a student and long after my own time. And if I have wondered what a difference it would have meant to me, a mere physiologist, to have had a surgical training under Lister, how much more would it have meant to Victor Horsley if he had come under the direct influence of this great surgeon. Instead of being Marshall's, he would have been Lister's house surgeon, and how greatly he would have benefited by the close relationship with Lister and how keenly he would have followed and assisted in his experiments those who best know both men can appreciate!

It is easy to speculate on the "might have beens"! Sufficient to know that as soon as he came into his own Horsley was foremost in his adoption of Listerian methods, and it was in consequence of this that that particular combination of surgery with physiology which I have given you as my first illustration of the mutual benefits they confer on one another came about. If Lister had come to University College in 1866 I should have learned his methods from the master himself, but I should in all probability have missed the opportunity of conjoint association with the colleague whose memory we are assembled to-day to commemorate, and whose loss not only to physiology and surgery, but to the whole nation, will be felt for many a year.

ENCEPHALITIS LETHARGICA:

SOME OBSERVATIONS ON A RECENT OUTBREAK.*

By C. O. STALLYBRASS, M.D. Lond., D.P.H.,
ASSISTANT MEDICAL OFFICER OF HEALTH, LIVERPOOL.

It is now six years since von Economo drew attention to the occurrence in Vienna of a disease which had hitherto, in this generation, escaped record, with the exception, as it would appear, of certain isolated and sporadic cases; several of the latter were described about the years 1903, 1907, and 1913,[1] but their significance was missed. There was an outbreak in France at the same time as the Vienna epidemic, but its nature appears to have escaped attention at the time. Since 1917 the disease has spread pandemically throughout the world. It has become in many places as common as enteric fever, though as fatal as unmodified small-pox; its clinical manifestations are protean. The sequelæ and residua are frequent and severe, and render the individuals affected useless to the community. The problem of its prevention is as yet unsolved. It was stated,[2] as late as March this year, that "it would appear as if the disease had spent its epidemic force during the winter of 1920–21, and there was reason to think that it had become less malignant in its clinical manifestations." This is far from being the case, for there have been recrudescences this winter in our two principal western seaports—namely, Glasgow [3] and Liverpool—as well as in New York and other parts of America, which have exceeded in severity the previous outbreaks; as many as 88 cases have been notified in New York City in one week in February.[4] Czecho-Slovakia and Sweden, among European countries, have also suffered severely.

Incidence in Liverpool.

This paper is mainly based on 127 Liverpool cases, the great majority of which have come under my personal observation, and of all of which full notes have been kept. The numbers of cases notified in Liverpool in successive years from 1919 onwards have been 2, 17, 27, and 5. Up to the end of April this year 76 cases have been reported—more than the total for the antecedent four years. Taking the onset of the disease, the cases reached a maximum in the last week of January. Moreover, during the same period about 30 cases have been reported in the districts immediately adjacent to Liverpool, and having a population aggregating some 500,000 persons.

Prior to this year cases mainly occurred in little groups associated in time and space. This year cases have been widespread, occurring simultaneously throughout the city and surrounding areas; the conflagration occurred in a population already widely infected, so it would seem, but yet localised to the vicinity of Liverpool.

Within the last 12 months there has been a change in the type of the disease, which has become more severe and oftener fatal, the fatality rates for the years 1920 onwards having been 12, 22·5, 40, and 39 per cent. respectively. The fatality rate for the last year and a quarter is double that for the preceding two years. These rates compare favourably with those for the country generally, but this is perhaps due to more complete notification in Liverpool, as in other teaching centres. It must be recognised that the clinical type of the disease has somewhat altered, and that the cases which from the prominence of the feature of lethargy led von Economo to name the disease encephalitis lethargica and evoked its popular paraphrase of "sleepy sickness" now form but a portion of the whole; these terms are misnomers. This change of type occurred in Italy and France as early as 1919. In 1921 the majority of the cases occurring in Liverpool (81 per cent.) could still be classified as "oculo-lethargic" in type, and the most prominent symptoms were (*a*) lucid somnolence—i.e., lethargy from which the patient could be roused; (*b*) mask-like facies more or less marked and expressing the patient's mental apathy; (*c*) voice changes, the voice like the face often becoming tired, expressionless, and toneless, though thick and slurring speech is not uncommon; and (*d*) eye signs, especially early and transient diplopia, semi-ptosis, nystagmus, squint, fixation, inequality or irregularity of the pupils, and cycloplegia. Other paretic signs, such as facial paresis or dysphagia, might be present. Constipation was common; the most prominent symptoms were on the side of defect or depression of function—i.e., lethargy, somnolence, and paresis. Nevertheless, tremors, jerky movements or delirium were often added to the picture, and in five out of 17 cases notified in 1920 myoclonus, general convulsions, or choreiform movements were present.

Altered Type of the Disease.

This year the picture has considerably changed. Less than half the cases—i.e., 45 per cent.—can be classified as oculo-lethargic owing to the occurrence of lethargy (usually associated with ocular paresis) at some stage, the remainder have been frankly myoclonic (14 per cent.), choreiform (25 per cent.), or psycho-motor (16 per cent.) in type. Instead of lethargy there was often extreme restlessness and excitement, sometimes delirium of a wild and unrestrainable type; instead of somnolence there was prolonged sleeplessness; instead of or in addition to paresis there was myoclonus (80 to 100 contractions per minute), or other form of hypermotility, often associated with severe pains; whole groups of muscles—e.g., of the shoulder girdle or of the diaphragm and abdominal muscles—may be affected, and a coördinated series of movements may be performed. Many cases present irregular jerky movements or twitchings, and these merge into the cases presenting choreiform movements in which chorea gravis is closely mimicked, except that the movements persist during sleep. Some of these unfortunate persons present symptoms of an extraordinary type; one boy—brother of a lethargic case—was described as leaping from all fours into the air, the movements resembling those of the mechanical toys sold by pavement vendors as "jumping beetles." Another boy when seen by me had both eyes rolling with great rapidity in one direction, his tongue rolling in his mouth in the opposite direction, the while the remainder of his face was contorted by a ceaseless succession of grimaces. He was in a state of extreme terror which was clearly depicted on his face. If asked a question he would answer rationally and then resume the grimacing. A most distressing symptom in some cases was tachypnœa—a respiratory rate of 80 per minute for a fortnight or more in two cases.

One of the characteristics of the disease, especially of the recent cases, is the frequent occurrence of delirium of an occupational form. There is disorientation both as to time and space, somewhat as may happen in delirium tremens; the person thinks he is or ought to be carrying on his ordinary occupation. A painter continually performed the movements of painting; a sailor out of work got up in the middle of the night to look for work; a servant girl got up at a similar hour and lit the kitchen fire, only realising the absurdity of the action when it was completed; a child whose duty it was to look after a baby rolled up a bundle of towels and nursed them; a ship's quartermaster, when surrounded by anxious relatives, believed himself to be in the saloon of the ship among the passengers. It is, however, often a feature of the delirium—as of the lethargy—that the patient can be roused to reason for a brief period by a sharply put question or command.

---

* A paper read before the North-Western Branch of the Society of Medical Officers of Health.

The whole aspect of the disease has developed in the direction of hyperactivity of the brain rather than depression. Even the cases classed as oculo-lethargic more often than formerly present at some stage of the disease, the features of sleeplessness, excitement, delirium or hypermotility. The occurrence of myotatic irritability, or of exophthalmos, of vertigo, or of waxy flexibility, and occasionally scarlatiniform or purpuric rashes, have also been noted here. In describing a case one frequently finds oneself employing terms implying the imperfect development of a sign or symptom such as semi-ptosis, transient paresis, nystagmoid movements, and so forth.

Difficulties of Diagnosis.

Certain cases give rise to special difficulty. Tumour or abscess of a "blind area" of the brain is one of the most difficult to distinguish, though the ophthalmoscope assists greatly; but even with this aid the diagnosis may be in doubt; optic neuritis may be present in encephalitis lethargica and absent in cerebral tumour. Examination of the cerebro-spinal fluid may be of considerable value; cerebro-spinal fever and syphilis may be excluded by cytological examination and by the Wassermannn test; in encephalitis lethargica the cells present are lymphocytes and few in number. Separation from tuberculous meningitis may be difficult, and here the estimation of the sugar content of the cerebro-spinal fluid is of great assistance—the normal content is about 60 mg. per 100 c.cm.; in encephalitis we have not found it lower than 68 mg. and the average is about 75; in tuberculous meningitis it is always below 60 mg. In two recent cases of the latter disease, which were notified as encephalitis lethargica, it was 43 mg. in the first case, and in the second was given on two examinations as "sugar much reduced" and "sugar absent," tubercle bacilli being found at the second examination. A tuberculous encephalitis may be otherwise quite indistinguishable. We are much indebted to Dr. R. Coope, who has carried out the estimation in a number of cases. It is essential that the estimation of sugar should be made by a competent bio-chemist, and that the fluid be examined promptly, especially in summer. Mild or abortive cases, especially in children, present great difficulty, and there can be little doubt that many of these cases occur but escape observation.

Residua and Sequelæ.

One of the gravest aspects of the disease is the frequency of residua and sequelæ. Not only is the mortality heavy but in a high proportion of cases the brain is permanently damaged. The sequel noted most frequently is "Parkinsonianism" or symptomatic paralysis agitans, from which disease it is distinguished by its occurrence in persons aged 10 to 40 years old, as a rule, and by the absence of the pill rolling movement. The picture presented by the combination of a rigid, mask-like face, slow speech, drooling of saliva and anthropoid gait, &c., are very characteristic, if not pathognomonic, and often enable a diagnosis to be made retrospectively. Other residua are myoclonic and also slow rhythmic movements; psychoses, such as dementia præcox; and alterations in character and temper, a well-behaved child becoming a "perfect little monkey." One of the conditions seen has been an inversion of day and night, the person being awake all night in a restless and excited condition and only dropping off to sleep towards morning and may then spend the greater part of the day sleeping. These sequelæ may begin to develop immediately after apparent recovery from the acuter symptoms, or may not appear for one, two, or more years.

Relapses.

Another serious feature is a liability to relapse, the acute symptoms being reproduced; the recurrence has usually been at the time of year when the disease is most prevalent—one case of the series relapsed two years after the first attack. An analogous event is the occurrence of two or three cases which only became acute this winter, but gave histories of ill-defined nervous disease going back to the preceding summer. Another patient, a boy of 12 years, who had developed a well-marked nystagmus exactly 12 months before, underwent a definite attack in February of this year. These cases point to climatic changes markedly affecting the susceptibility to the disease. Another case in point is that of a sailor who went on a voyage to the West Indies, lasting five weeks, during which time the crew did not leave the ship. He fell sick with encephalitis three days before reaching this port. Here we must presume the infection was latent on the vessel until she returned from a warm climate to a cold one. The sudden change of temperature apparently increased the susceptibility to the disease. This phenomenon has often been observed in the case of beri-beri; in vessels so affected often no cases will develop until they reach cold weather, when a considerable number will fall ill in rapid succession. Undoubtedly the virus of encephalitis may persist for prolonged periods, and recurrence of symptoms may perhaps be associated with recurrence of infectivity. In view of the liability to residua and relapses prognosis must be most guarded.

Epidemiology.

The earlier reports laid stress on the sporadic character of the disease and the scarcity of multiple cases in a family. It appeared as if the susceptibility to the disease was very low and that carriers were probably numerous. The outbreak in the Derby girls' home, in which 12 persons (of whom five died) fell ill in a population of 22 persons of susceptible age, pointed to the possibilities of the disease. Of like character appears to have been an outbreak in an asylum at Mulheim last summer. Here 28 cases with 13 deaths occurred in 20 days, six being nursing sisters and two doctors. John and Stockebrand, who reported[5] the outbreak, considered that it was not one of encephalitis lethargica but a new disease; basophil stippling of the red blood corpuscles was present in all cases. Botulism was excluded. Dysphagia and ophthalmoplegia were frequent symptoms; the outbreak was probably one of encephalitis lethargica of an aberrant type due to a virus of enhanced virulence. Fyfe[6] has described four ambulatory cases in a school. Kling and Liljenquist[7] have described an epidemic in Lapland, from 7 to 45 per cent. of the inhabitants of the stricken villages being affected; in one household all the members were affected. Cases of simple malaise with little or no focal symptoms were numerous.

In all these outbreaks abortive or larval forms have been more or less numerous. It is probable that there are a considerable number of missed cases even of the typical form, as the disease is by no means always recognised, and it would appear from the instances to be cited that case-to-case infection is not infrequent.

A fatal case occurred on Nov. 27th in a male aged 21 years. His sister, aged 13 years, who had previously suffered from chorea, fell ill with what appeared to be a relapse about Christmas. On Jan. 31st she became worse, her temperature rose to 100·5° F. and diplopia and severe headache were complained of. An acquaintance, a boy of 15 years, who lived in the same street, was taken ill on Dec. 26th with a typical lethargic attack and was removed to hospital on Jan. 7th. On Feb. 2nd a case occurred in the immediate vicinity of the street, but no history of contact could be obtained. On March 29th one of the school medical officers drew my attention to a child aged 7 years, who lived in the next street, and who had been suffering from lethargy since Feb. 15th. Inequality of the pupils was still present, and the child displayed a change of temperament; she had used abusive language to her mother and threatened her with a knife, though previously of a quiet disposition. This child was acquainted with the family of the first two cases. Here we have, in a very small area, a series of five cases of which four were acquaintances. Another couple of cases in a family have already been referred to; a case had previously occurred in the same street a few doors off, but there was no direct communication with them.

A railwayman was taken ill with symptoms of neurasthenia last Christmas. On April 16th he suddenly developed an acute choreiform attack which has since proved fatal. Another railwayman, well known to him, who lived in the next house, but had been ill from September to December with abdominal pain and vomiting, in December developed diplopia, choreiform twitchings, and delirium, and was sent in by his medical attendant as a case of encephalitis lethargica to an institution where he died on March 29th. Whether infection was derived by the first case from the second, or vice versa, is difficult to say, owing to the long latent periods in both cases.

A teacher at an elementary school was taken ill on Feb. 8th. She returned next day to her home outside Liverpool, and I am informed that she suffered a typical lethargic attack. In the same week her four co-workers in the infants' department were affected with severe headache, nausea, and drowsiness, but no catarrhal symptoms. One of them suffered from a temporary but marked dimness of vision, probably due to a cycloplegia. There is evidence here that personal case to case infection is not infrequent, and that missed cases and mild and abortive cases, also cases during the sometimes prolonged latent period, are factors in the spread of the infection. It is probable that if all the mild and abortive cases were known we should be less inclined to speak of the sporadic distribution of the others.

Susceptibility.

There are clearly great variations in the susceptibility to the disease. The susceptible age is especially the decade from 10 to 20 years, though among this series are cases aged from 5 months to 70 years. The disease, therefore, differs from other notifiable diseases in that the greatest number of cases occur at an age when practically all infectious diseases, including epidemic encephalitis tself, are least fatal. This inverted relationship is well shown in the figure, drawn mainly from statistics given in the Ministry of Health's recent report.[8] There is no special sex liability, though pregnant women appear to be specially susceptible; three were affected this year, but their offspring were not. Choreiform cases may be very difficult to distinguish from chorea gravidarum. Seasonal influence is very marked; cases begin to appear about October or November, increase in December, and reach a maximum about the end of January or beginning of February. For reasons already given, this seems to be due to an increased susceptibility of the individual. The small summer outbreak of 1920 appears to have been exceptional.

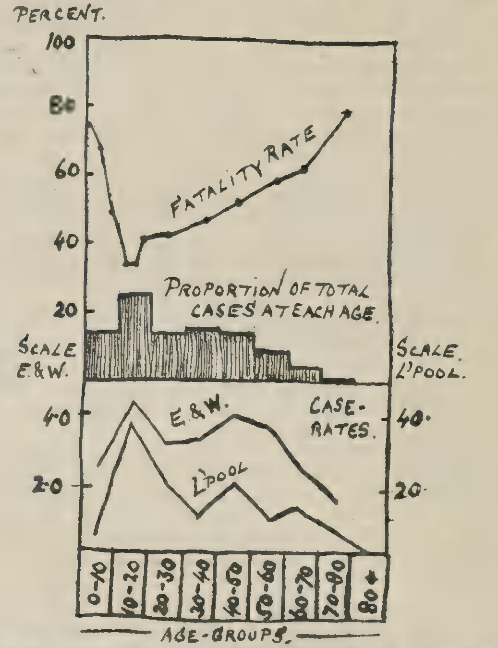

Chart based mainly on statistics given in the Report of the Ministry of Health, No. 11 (1922), showing inverted relationship of age incidence and fatality of encephalitis lethargica.

Previous injury to the brain, &c., appears strongl to predispose. Three cases had recently suffere from a fairly severe blow on the head. One patien had a long-standing dorsal kyphosis. Another ha suffered from chorea. In still another case a girl wa taken ill the day after the extraction of a number o teeth under anæsthesia, which animal experiments show definitely to precipitate an attack. Encephaliti seems to predispose to certain secondary invaders apart from the late occurrence of broncho-pneumonia in two cases diphtheria developed, in one scarle fever, and in another erysipelas. Septic infections ar rather frequent. In two cases the first symptom were those of pneumonia.

Association with Other Diseases.

There is still some discussion as to whether epidemi encephalitis is a specific infectious disease. The ag and seasonal incidences clearly demarcate it fron poliomyelitis. The views expressed by Crookshanl and others that it has some connexion with influenz find no support in the cases under review.

In only four of this year's cases was there history of influenza within six months preceding th onset, and two, both from the absence of catarrha symptoms and on the admission of the medica attendant, were not genuine influenzal attacks, bu merely the onset of encephalitis with pyrexia but n localising symptoms. The extensive wave of influenz during the spring of 1922 was accompanied by n corresponding increase of encephalitis, but rather th reverse. In Liverpool, if there is any relationshi between the diseases it is inverted, as encephaliti would seem to prevail mostly in years when influenz is in abeyance, as in the present year. The productio of an encephalitis resembling Economo's disease, an *not* a meningitis caused by Pfeiffer's bacillus, whe the filtrates of influenzal sputa are intrathecall injected into rabbits, requires confirmation, and doe not appear crucial in any case.

Until more definite evidence is forthcoming th association of influenza and von Economo's diseas may be regarded as fortuitous or non-existent. What then, are the factors that have produced the presen pandemic ? Has some local exaltation of the virulenc of the organism—as, for example, happened at Derb and ex hypothesi at Mülheim—produced a virulen strain, for the spread of which the world war provide most favourable conditions, notably the unprecedente movements of the millions of troops ? In that cas are we to conceive that, prior to the present pandemic invisible epidemics affected the population and presumably immunised them, but only here and there where extremely susceptible individuals were attacked produced recognisable cases ? But the shape of th curve of age distribution of cases is against an hypothesis of such a widespread immunising epidemic unless that immunity produced were but of shor duration ; this might well be, though it would brin this disease into sharp opposition with most of th other ectodermoses—e.g., small-pox, chicken-pox, an poliomyelitis ; and yet vaccinia, which is so closel allied to variola, produces an immunity which fade with the lapse of time.

Or, on the contrary, is it the infectivity of th organism that has increased ? Or have infectivit and virulence been simultaneously enhanced ? A least it is clear, seeing that we are dealing with world-wide pandemic, that it is *not* merely due to diminished resistance on the part of the human host though this may have been a factor in the origina alteration of the virus of the disease.

Whatever the origin of the disease, we are witnessin an epidemic apparently affecting a virgin populatio —an epidemic which, further, appears to be in cours of evolution. The besiegers of the castle are alterin their tactics in full view of the besieged. This is a epidemiological event of sufficient infrequence t warrant the closest attention being paid to it.

My thanks are due to Prof. E. W. Hope for permission to publish these observations, and to th medical men in all the Liverpool hospitals and als in general practice who have freely permitted me to visit and make notes of their cases and have provided me with detailed information concerning them.

TWO CASES OF UNILATERAL ŒDEMA WITH ALBUMINURIA.

BY JAMES W. RUSSELL, M.D. CAMB., F.R.C.P. LOND.,

PHYSICIAN TO THE BIRMINGHAM GENERAL HOSPITAL; JOINT PROFESSOR OF MEDICINE IN THE UNIVERSITY OF BIRMINGHAM.

THE following cases of unilateral œdema with albuminuria afford considerable opportunity for discussion.

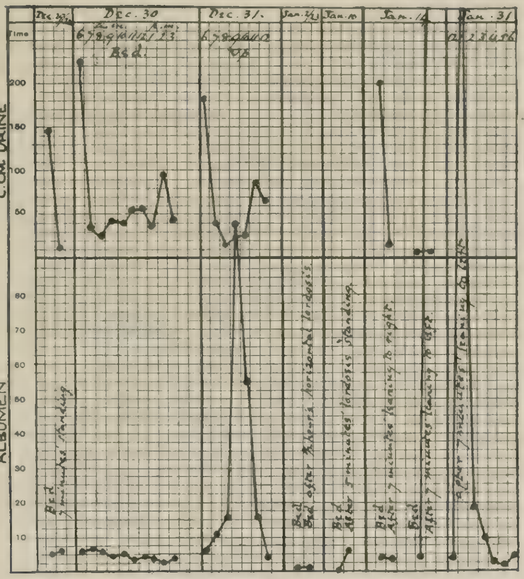
CASE 1.—In August, 1922, a teacher, aged 40 years, came to consult me complaining of swelling of the left foot of six years' duration, which only gave her serious inconvenience in the hot weather. Very occasionally the right foot was also a little swollen. For the same period she had been feeling tired and had suffered from headache. Her doctor informed me that the urine invariably contained albumin, and he called my attention to the presence of a systolic murmur at the apex of the heart. On examination there was definite œdema of the left foot. There were no visible varicose veins, and the right foot was free from œdema. The urine contained a haze of albumin, but no casts were to be seen in the centrifugalised deposit. The pulse was slow and regular and the heart was not appreciably enlarged, though the apical systolic murmur was well marked. The diastolic pressure was 76, the systolic 142. I made some entirely unsatisfactory suggestion as to the possible presence of deep-seated varicose veins, but I realised that I had in no way solved the problem of the diagnosis, and put the case aside in my mind for future reference should occasion arise.

CASE 2.—Towards the end of December a girl, 19 years of age, was sent into one of my wards in the Birmingham General Hospital with œdema of the left foot and albuminuria, the former of nine years' duration. The right foot was said to be occasionally slightly swollen, though no œdema was seen during her stay in hospital, and she volunteered the statement that the left-sided œdema was worse in the summer than in the winter. The heart was normal, as was the blood pressure for the age, and no casts were at any time discovered in the urinary deposit. There were no varicose veins.

For the first few days the patient was kept in bed, and the œdema of the left foot gradually subsided, though it invariably returned in the upright position. The urine in bed contained only a trace of albumin. A series of observations were then made with regard to the albuminuria, the results of which are recorded in the chart (Fig. 1). The albumin measurements are made in terms of the "unit" of albumin, slightly modified, recently described by me in a paper on orthostatic albuminuria[1]; a brief account of the method is appended at the end of this communication. The "unit," as I now make it, is an exceedingly small quantity, and amounts, I believe, to about 0·002 per cent. of dried egg albumin, or a little less, but I do not claim for it any absolute value. The upper series of curves record the volume in cubic centimetres of the specimens of urine examined.

On Dec. 29th the urine passed in bed contained 5 units of albumin. The patient then stood upright for 7 minutes, got back to bed, and passed urine again. This specimen contained only 6 units of albumin. On the 30th hourly specimens were passed in bed from 6 A.M. to 3 P.M., 10 oz. of fluid being taken at 6, 8, and 10 A.M. and 1 P.M. The urine excretion shows a considerable failure of diuresis, and the curve of excretion somewhat resembles that which I have described as often met with in cases of orthostatic albuminuria. The albumin content varied only between 3 and 6 units. On the 31st she was up and about the ward from 6 A.M. to noon, passing urine at intervals of an hour. The quantity of albumin steadily increased, until at 9 o'clock it amounted to a thick cloud (100 units). It then as steadily diminished, and at noon only 4 units were measured. The quantity of urine showed but little relation to the amount of albumin contained. These observations were repeated a few days later with much the same result, although the albuminuria of the upright position was not quite so large as before, but again it showed the striking early rise, with a drop towards middle day, and this was noted on several other occasions. The larger degrees of albuminuria were therefore mainly of the orthostatic or postural variety, although it is noticeable that the bed urine was seldom free from protein, that the big rise in the albumin excretion always took two or three hours to develop and came to an end by noon, and that the response to 7 minutes' standing was extremely slight.

FIG. 1.



Case 2.—Albumin measurements in units, and volume of specimens of urine examined.

The question of a possible lordosis was then investigated. On Jan. 2nd the patient lay in bed in a position of artificial lordosis for the space of half an hour. The urine, before and after the experiment, contained only 1 unit of albumin. She then stood for five minutes in a position of extreme lordosis. The urine passed immediately afterwards contained 5 units, a much smaller amount than is generally produced in this position in cases of orthostatic albuminuria. An X ray photograph of the spine showed complete absence of lordosis and a marked lateral curvature with the lumbar convexity towards the left. The latter was obvious to external examination.

I was aware that Vorpahl[2] had described a case of orthostatic albuminuria in a patient with lateral curvature in which catheterisation of the ureters had shown that the albumin came from the right kidney only, and, although I did not feel that this procedure was justified in my own case, I thought that some light might be obtained on the question by further postural observations.

On Jan. 14th the patient passed urine in bed containing 4 units of albumin. She then stood for 7 minutes leaning well over towards the right, so as to accentuate the lumbar convexity of the spine. The urine at the end of the experiment contained rather less albumin than before. She then stood for the same time leaning in the opposite direction, with the result that the urine passed immediately after getting back to bed was almost solid with albumin, no less than 600 units being measured. On Jan. 31st the observation was repeated with much the same result. She remained up, and an hour later the albumin had fallen to 18 units, and an hour later still to 10. For the next three hours the urine was almost free from albumin.

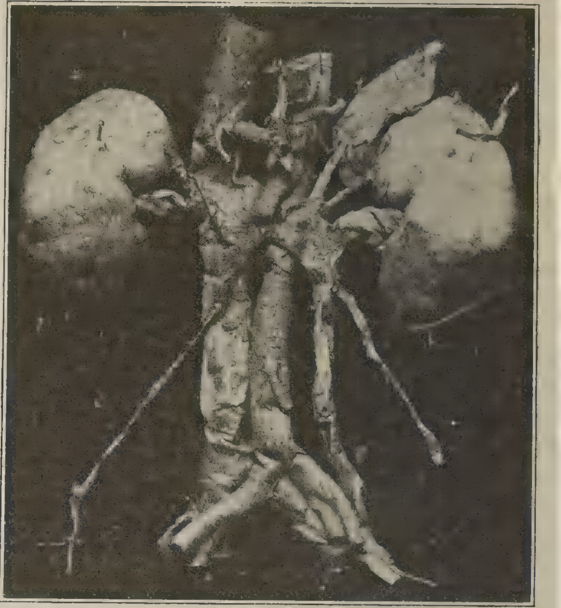
[2] Berl. klin. Woch., May 2nd, 1910.

Although the final proof of catheterisation of the ureters is not forthcoming, it seems to me that these experiments afford good reason for believing that the albumin was coming from one only of the two kidneys, but which of the two is involved must remain a matter of uncertainty. It is to be noticed that in Vorpahl's case, in which the lumbar convexity was apparently towards the left, the albumin was found to be coming from the right kidney. But Dr. Parkes Weber [3] has called attention to several observations showing that in orthostatic albuminuria the albumin not infrequently comes from the left kidney only, and I think that the left-sided œdema in my own case makes this a probable assumption. The case to be quoted below also supports the left-sided origin of the albuminuria.

The question of the relationship between the œdema and the albuminuria now arose for consideration. It will be remembered that in both my cases the œdema was practically confined to the left foot and leg, and Dr. Weber [4] refers to a case described by R. Ehrmann [5] of a young man, aged 20 years, with albuminuria and chronic œdema of the left leg, in which catheterisation of the ureters showed that the albumin was coming from the left kidney only. I know of no other recorded case, and one must assume, in the absence of evidence to the contrary, that there is some special reason for the limitation of the œdema to the left side. When I showed my case at the Midland Medical Society [6] the suggestion was made that there might be a single large kidney, in some way causing venous obstruction, but this suggestion is negatived by the fact that I and some of my colleagues have felt both kidneys in their normal position. Being unable to devise for myself any explanation of the association, I referred the problem to Prof. J. C. Brash, and he at once proposed an exceedingly ingenious and, as it seems to me, quite possible solution of the difficulty. Prof. Brash informs me that there is frequently a small vein running vertically between and connecting the left iliac and renal veins, and that this vein represents either the left post-cardinal or the left supra-cardinal embryonic vein.[7] Sometimes this vein is found of larger size, and in these cases the post-renal portion of the inferior vena cava may be correspondingly diminished. Indeed, occasionally this portion of the inferior vena cava may be entirely transferred to the left side, and under these circumstances the whole of the blood from the lower extremities must pass into the left renal vein in order to reach the general portion of the vena cava. Prof. Brash suggests that if the post-renal portion of the inferior vena cava were in this way duplicated to a considerable extent, so that the blood from the left leg, and perhaps some from the right leg, passed into the left renal vein, then any obstruction of the latter would tend to produce an albuminuria with œdema of the left lower extremity, and occasional œdema of the right foot also. The accompanying photograph (Fig. 2), for which I am indebted to Dr. J. F. Brailsford, is made from an anatomical preparation lent by Prof. Brash for reproduction in this paper, in which such duplication is present. If this condition were carried a little further, I think that an adequate explanation of the association of left-sided œdema with albuminuria would be forthcoming, assuming the existence of some obstruction of the left renal vein. The simultaneous occurrence of this anatomical peculiarity with a lateral curvature—again assuming that the curvature is the cause of the venous obstruction—would, of course, be a rare event, but these cases must be very rarely met with if it be really true that up to the present time there is only one on record. Whether albuminuria often occurs in cases of lateral curvature I do not know. A few cases have been kindly sent me by my surgical colleagues, and in only one was albumin present in the urine. In that case a slight cloud was found on the first examination, but on a subsequen occasion neither standing in the upright position, no leaning to either side, produced any albumin. Th cases are, however, too few in number for any definit statement to be based upon them. The anatomica explanation suggested above is, of course, only a surmise, and demonstration of its truth or the revers must await the opportunity of post-mortem examination. It would be interesting to know whether, in th cases of orthostatic albuminuria with albumin comin only from the left kidney, to which Dr. Parkes Webe calls attention, there was any lateral curvature of th spine.

Fig. 2



Photograph by Dr. Brailsford of anatomical preparation lent by Prof. J. C. Brash, showing duplication of post-renal portion of inferior vena cava.

Even if this be the correct explanation, the problems raised by my two cases are not at an end. Both my patients volunteered the statement that their œdema was definitely worse in the summer, and I have recently heard that, during my temporary absence from hospital, the second patient came up complaining of a fresh increase in the œdema (June, 1923). I have not, however, had an opportunity of confirming this by actual observation. Increased sweating might account for an apparent increase in the albuminuria, if it occurs, but it is difficult to see how that can be invoked as an explanation of the increase in œdema. This new type of "cyclical variation" is difficult to explain, as is the marked tendency in my second case for the albuminuria to occur in large quantities for a brief period after getting up. In the more typical cases of orthostatic albuminuria it is well known that the albuminuria may come to an end in the late afternoon, and in the paper previously referred to[1] I have brought forward some evidence to show that this is not due to an adaptation to the upright position gradually acquired in the course of the day. But in none of the cases of which I have records have I come across this persistent isolated rise in the albumin output taking place a few hours after getting out of bed. Why the effect of the upright position should take from two to three hours to establish itself I do not know, but the subsidence in the morning of Dec. 31st and in the afternoon of Jan. 31st does suggest that it may here be a matter of adaptation. Again, the œdema in my first case did not set in until the patient was 33 or 34 years of age, and had only been present for 10 years in the second. In the latter the scoliosis may possibly have been of recent origin, but I doubt if such an explanation would be likely to apply to the elder of the two patients, and again I do not know that in that case any scoliosis was present. In the paper already quoted I have given some reasons for thinking that orthostatic albuminuria is not purely mechanical in origin, and that in many cases at any rate some slight renal damage has probably occurred. It may be noticed that my first patient had complained of feeling tired and of headache during the period over which the œdema had lasted, but there was no history of any preceding illness.

I may conclude my paper by briefly describing the method of albumin measurement adopted in constructing the above chart. The method is described in detail in the *Quarterly Journal of Medicine*[1] and is based upon the comparison of the coagulated albumin with a standard haze.

Three stock solutions are used: (1) N/500 barium chloride solution in distilled water; (2) N/500 magnesium sulphate solution in distilled water; and (3) distilled water, to every 100 c.cm. of which are added 0·04 c.cm. of saturated picric acid solution in distilled water and 0·02 c.cm. of freshly made 0·2 per cent. Bismarck brown. Solutions 1 and 2 are kept in bottles previously treated with strong hydrochloric acid and a crystal of thymol is added to prevent bacterial growth.

In order to produce the standard haze, which constitutes the "unit" of albumin, half a cubic centimetre each of solutions 1 and 2 are mixed together in a flat-bottomed tube of thin glass, 15 cm. in length, with an internal bore of 1·1 cm., made for me by Messrs. Philip Harris, of Edmund-street, Birmingham. The mixture is allowed to stand for five minutes, and 8 c.cm. of solution 3 (5 c.cm. in the original paper) are then added. The albumin estimations are made by measuring a known quantity of the boiled albuminous urine, with the addition of a few drops of saturated salicyl-sulphonic acid solution, into another tube of the same size, and diluting with water pigmented as in solution 3 until the hazes in the two tubes match one another, care being taken that the degree of pigmentation in the tubes is kept as nearly as possible the same. In dealing with a heavily albuminous urine, at least a tenth part of the salicyl-sulphonic acid solution must be added to the urine, and this dilution must be allowed for in the calculation. The number of dilutions needed in order to match the two hazes gives the measure of the amount of albumin contained in the urine. I should add that to arrive at the highest possible degree of accuracy, the specific gravity of the specimens examined should be brought to a fixed point, as is the case with the Esbach albuminometer.

This method does not pretend to attain strict scientific accuracy, but I have shown that with care a close approximation to the truth, and a reasonably correct picture of the output of albumin, however small, can be obtained. The advantage over the Esbach method, apart from the abolition of the 24 hours' standing, lies of course in the fact that the standard haze method is applicable to the small, as well as to the large degrees of albuminuria.

A CASE OF
CORTICAL NECROSIS OF THE KIDNEY
WITH POLYARTERITIS ACUTA NODOSA.

By E. WORDLEY, *M.C.*, M.B., B.Ch. Camb.,
M.R.C.P. Lond.,
PATHOLOGIST TO THE SOUTH DEVON AND EAST CORNWALL HOSPITAL, PLYMOUTH.

THE following case is brought to notice on account of the extreme rarity of the association of these two conditions. The term polyarteritis acuta nodosa was introduced by Ferrari (1903) to describe a group of cases having all the symptoms of an acute febrile illness, the lesions found post mortem being multiple nodular swellings in the smaller arteries. A summary of the cases described up to 1907 is given by Carnegie Dickson, who differentiated between periarteritis nodosa, which is almost always of a syphilitic origin, and polyarteritis acuta nodosa, of which he collected 16 samples from the literature in which syphilis was apparently not the causal agent. He also describes in detail a case which came under his own observation, giving drawings of the vessels and the microscopical appearances. In his own case and in several of those quoted, one of the principal symptoms at the onset of the disease was acute abdominal pain. In his own case there was present definite evidence of a past tuberculous infection in the shape of caseous mesenteric glands.

An additional case is described by Beattie (1912) in which again the picture was that of an acute febrile disease in which post mortem the lesions present were multiple nodular swellings of the smaller arteries. Microscopical examinations in all these cases showed the middle coat of the arteries to be most affected. In these cases described by both Carnegie Dickson and Beattie, the kidney showed thrombotic areas and acute nephritis but not cortical necrosis. With regard to the condition of cortical necrosis of the kidney, this is also of considerable rarity. It has been met with chiefly as the complication of the later stages of pregnancy associated with symptoms of eclampsia, but is extremely rare in males. A case has been recently described by Bamfurth (1923). The patient, a soldier in the Salonica Force during the late war, was at the time suffering from malaria, though there was no evidence that this was in any way a contributory cause of the kidney lesion.

The following are the particulars of the present case:—

A boy, aged 13, was admitted on Nov. 25th, 1922, to the South Devon and East Cornwall Hospital, under the care of Mr. G. Robinson, senior surgeon, to whom I am indebted for permission to publish this case.

History.—A week previous to admission he had had very severe spasmodic pains in the right side of the abdomen with fever. This had persisted until on the day of admission he began to pass bright-red urine. Before admission he had noticed no blood in the urine and had passed a normal amount. No œdema had been noticed.

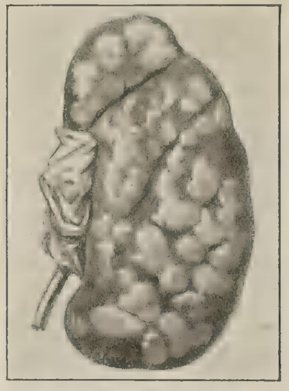
Condition on Admission.—He was rather pale, but otherwise of healthy appearance. No puffiness about the face; great tenderness below both costal margins, but no abdominal rigidity, and no tumour to be felt in the abdomen.

Course of Case.—On the day of admission he had nine fits within the hour, but soon after was perfectly conscious and showed no signs of drowsiness. On that day he only passed 1 oz. of urine. Temperature, 100·8° F.; pulse, 100. Shortly after admission abdominal pain was only slight and he began to pass more urine; four days after admission he was passing 2 pints a day. This amount steadily increased, until on the day before his death he passed over 4 pints. Blood pressure, 106 mm. Hg. Examination of the eyes showed no abnormality of the fundus. Examination of urine on Nov. 28th, 1922, showed a cloud of protein, a few red cells, leucocytes, and a few hyalo-granular casts. On the 29th estimation of the blood-urea gave 22 mg. of urea per 100 c.cm. blood, the diet at this time being almost entirely milk. On Dec. 7th the urine showed no evidence of blood to the naked eye. In the centrifugalised deposit there were a few red cells and leucocytes; no casts were seen; calcium oxalate crystals were numerous. Further examination of the urine on the 28th showed a cloud of protein, red cells, and leucocytes as before and fairly numerous granular casts. Cultures of the urine were sterile. A blood count on the 28th showed 16,200 leucocytes per c.mm., with a differential count as follows: Polymorphs, 82 per cent.; lymphocytes, 14 per cent.; large hyalines, 2 per cent.; eosinophils, 2 per cent.

Throughout, until the patient's death on Jan. 13th, 1923, as has been stated, he continued to pass between 2 and 3 pints of urine a day. No œdema was ever present. Latterly, the abdominal pain disappeared. He complained of no headache but ate badly, and slowly wasted. Towards the end the abdomen appeared rather distended and the superficial veins were prominent. At this period there was a diffuse systolic murmur heard over the base of the heart. There was no diarrhœa or constipation, the bowels acting regularly once a day. There was no vomiting. During the six weeks he was in hospital there was irregular fever with a maximum rise to about 101° F. There were no rigors. On two occasions there were slight transitory fits of about a minute's duration, until on Jan. 12th, the day before death, there were a series of prolonged and violent fits. The cerebro spinal fluid was then withdrawn by lumbar puncture. It was under considerable pressure. Microscopical examination of the fluid, which was quite clear, showed no excess of cells. The Wassermann reaction was not tested. The patient was one of a large family, his father and mother being both alive. Two brothers have been admitted to this hospital previously suffering from rheumatic endocarditis. The W.R. on the father's and mother's blood was performed. It was negative in both instances.

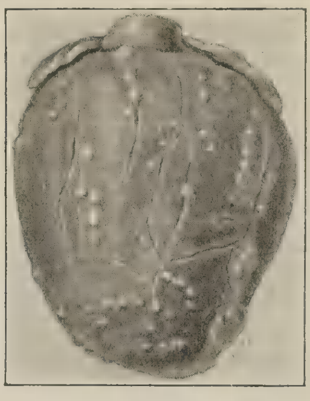
Post-mortem Examination.—Some clear fluid was found in all the serous cavities. The lungs were congested but otherwise normal. The heart was not enlarged; the valves were normal. Just about the tricuspid valves there was a small red swelling about the size of a pea. There was a similar swelling in the wall of the left ventricle. The coronary vessels showed numerous raised and thickened dilatations along all the smaller branches. The main trunks appeared rather thicker than normal, but were not dilated in the manner that the smaller branches were. The aorta was perfectly healthy. The stomach and intestines showed no abnormality, and the mesenteric vessels appeared normal to the naked eye. The liver and spleen, with their vessels, were normal. The kidneys were of normal size. The outer surface of both kidneys was studded with raised irregular whitish patches which resembled, at first sight, growth. On section, both kidneys showed a similar appearance. The cortical region was studded with these patches, many of them irregular in shape, but two were triangular, as is seen in infarcts. The ratio between cortex and medulla appeared normal. The portions of the cortex between these white patches were very deeply congested. The medulla appeared normal. The brain was normal. There was no hæmorrhage to be found and all the cerebral vessels were normal to the naked eye, showing no trace of the nodular appearance seen in the coronary vessels. Drawings of a kidney (Fig. 1) and of the heart (Fig. 2) show these appearances.

Fig. 1.



Showing necrotic patches in kidney.

Fig. 2.



Showing nodular swellings on smaller branches of coronary vessels.

Microscopical Examination.—A detailed description of the microscopical findings, with numerous plates, is given in the publications already referred to. Unfortunately, in this instance only the heart and kidneys were preserved for microscopical examination. Pieces of tissue were fixed in Kaiserling's fluid and embedded in paraffin. Sections were stained with hæmatoxylin and eosin, by Van Gieson's stain, and with methyl violet for amyloid changes. Sections were also stained with Giemsa and Leishman's stain, by the Gram-Weigert method, and by Levaditi's method for spirochætes.

Kidney.—In the necrotic whitish areas there was almost complete loss of structure of the kidney substance. These areas consisted of a mass of granular amorphous material with a faint indication of tubular structure. The epithelial nuclei were almost invisible. Scattered throughout these areas were numerous polymorphs and plasma cells and also numerous small masses of pigment. The zone just outside these necrotic areas showed a very considerable degree of increase in interstitial tissue with fibrosis. There was here considerable hæmorrhage, chiefly between the tubules. Nearly all the glomeruli in these non-necrotic areas were almost obliterated and replaced by fibrous tissue. Here were numerous areas of round-celled infiltration, and as in the necrotic portion there was extensive infiltration with polymorphs and plasma cells. The tubular epithelium was vacuolated and the nuclei stained rather poorly, but in this area the most obvious change was the glomerular one. In those areas, which appeared almost normal to the naked eye, the change, on the other hand, was relatively speaking nearly all tubular. Here the glomeruli were comparatively normal. There was thickening of the capsule and some hæmorrhage into the tufts. Throughout this area there was an intense degree of hæmorrhage, in a few places massive but chiefly between columns of tubules. The tubules in this area were largely denuded of epithelium and a large number were full of casts of hyaline material.

Vessels of the Kidney.—The vessels in general showed little change; there was a certain amount of thickening, chiefly of the media. A number of the smaller arteries were plugged with degenerated masses of red cells. In the necrotic areas a few vessels were seen in which there was an extreme degree of degeneration and inflammation of the coats and the lumen of these vessels was filled with organised thrombus. Sections of the renal arteries showed nothing more than a slight thickening and fibrosis of the middle coat; the other coats were normal.

Heart.—Section of the two small nodules in the wall of the heart already referred to showed them to be organised thrombi. Sections through the nodular enlargement of the small branches of the coronary arteries showed an extreme degree of proliferation and what appeared to be hyaline degeneration of all coats. In places they were not patent but obliterated by a mass of degenerated cells and organised clot. Section stained with Van Gieson's stain showed excessive fibrosis throughout the vessel. In many of the obliterated vessels no distinction could be made between the various coats. Round these obliterated vessels was a mass of small capillaries filled with blood and apparently carrying on a collateral circulation. There was also a considerable degree of perivascular inflammation round the affected vessels. Sections appropriately stained showed no evidence of amyloid degeneration. There was a fibrous myositis of the heart muscle. In none of the sections examined, stained by the various methods employed, were any micro-organisms seen.

Remarks.

The interesting features of this case are the most unusual combination of polyarteritis acuta nodosa with cortical necrosis of the kidney. The pathological findings have been described by others in full detail and the separate features in this case agree with those already described. That the disease is an acute infection seems obvious from its history and pathology, though so far no cause has been found. It would seem that in this case syphilis can be excluded. The history agrees in many respects with those quoted by Carnegie Dickson. It is curious that the boy should have had almost complete suppression of urine at first, after which a gradually increasing diuresis set in. Another curious feature of the case is that the arterial change was limited to the vessels of the heart, at any rate, as far as naked-eye inspection went. Also it is curious, considering the duration of the disease and the very extensive degeneration of the kidney, that no œdema was present throughout, and it is to be regretted that a chemical study of the kidney function was not performed at frequent intervals during the illness. The sudden onset with very acute pain and hæmaturia, and the absence of œdema, had at the beginning of the illness suggested stone as a possible diagnosis. Later the extreme wasting, the low urea content of the blood, and again the absence of œdema had suggested a neoplasm of the kidney. It is interesting to note that the acute symptoms described by Bamfurth in his case of cortical necrosis in an adult man—viz., the abdominal pain and fever—are in many respects similar to those described in cases of pure polyarteritis acuta nodosa, with the exception of the complete suppression of urine and sudden termination of the illness. The case here brought to notice in many ways is the combination of the symptoms found in the two diseases, and it is interesting to speculate if the pathology of the two is identical and the arterial changes the result of a more chronic type of infection. The case here described possibly offers some evidence for this view.

In conclusion, I should like to offer my thanks to Prof. L. S. Dudgeon for much advice and help in the preparation of this article.

TWO CASES OF BRAIN ABSCESS,

WITH REMARKS ON THE CYTOLOGY OF THE CEREBRO-SPINAL FLUID.

BY GEOFFREY HADFIELD, M.D. LOND.,
PATHOLOGIST TO THE BRISTOL GENERAL HOSPITAL AND TO THE BRISTOL MENTAL HOSPITAL.

THE clinical diagnosis of abscess of the brain frequently presents great difficulty, especially in its earlier stages, and an examination of the cerebro-spinal fluid often affords the clinician no positive evidence, for when the fluid is clear, it may show no obvious abnormality, whilst in the final stage, when the abscess has discharged, or is leaking into the sub-arachnoid space, the fluid so closely resembles that of septic meningitis as to be almost indistinguishable from it.

The following two cases of cerebral abscess in children are reported with a two-fold object: first, as illustrating the value of a careful differential count of the cells of the fluid during the stage when this is still clear, and secondly, to put on record their rather unusual morbid anatomy.

CASE 1.—Female, aged 8, who had suffered from chronic suppurative otitis media for two years, was in fair health until seven weeks before her death. She then developed a progressive illness, with a fairly sudden onset, symptoms developing in the following order:—

Condition on Admission.—She was mentally confused, had continual headaches, general tenderness, photophobia, and rigidity of the posterior cervical muscles. No sign was found which suggested localisation of the lesion to any particular region of the brain. Both tympanic membranes were found perforated and 1·5 D. of swelling was found in each optic disc.

Course of Case.—During the first fortnight she developed attacks lasting several hours, during which she became semi-conscious with a meningeal cry, and had frequent vomiting, severe enough to produce ketosis. During the second fortnight the bouts of semi-consciousness became longer, and she was more difficult to rouse. Kernig's sign appeared. The patient developed an acute coliform cystitis, which rapidly progressed. During the third fortnight signs of pyelo-nephritis developed, and she was found to have slight œdema of the face. During most of the day she was semi-conscious, and for hours at a time she could not be roused. During the last week she had several convulsions with rigidity of the left arm and twitching of the face and limbs. The renal complication progressed rapidly, giving rise to high fever and considerable emaciation.

Cerebro-Spinal Fluid.—Two days after admission a lumbar puncture withdrew clear fluid under moderately increased pressure, having the following characters: clear, even when illuminated from the side by strong light against a black background; colourless, against a white background; contains 12 cells per c.mm., 70 per cent. of which are polynuclears. Total albumin and sugar content within normal limits.

A tentative diagnosis of cerebral abscess (approaching the ventricular system or the sub-arachnoid space) was made from the above finding in conjunction with the clinical signs. Fourteen days after this examination the fluid was again examined with the following result: Fluid still clear and colourless; cells, 40 per c.mm., 80 per cent. of which are polynuclear; total protein, 0·06 per cent. (normal upper limit 0·03 per cent.); dextrose, within normal limits. A week later the fluid was slightly opalescent by strong indirect illumination, but not coloured. It contained 50 cells per c.mm., 60 per cent. of which were polynuclear, whilst a fortnight before death the fluid was obviously opalescent and contained 580 cells per c.mm., of which 0 per cent. were polynuclear, its sugar contents remaining within normal limits.

Post-Mortem Examination.—A small abscess (about the size of a pea, containing thick yellow pus) was found in the substance of the optic thalamus. Its boundaries were well defined, but there was no well-formed capsule. At its inner edge a reddish streak led from the abscess towards the lateral ventricle. On section this streak proved to be thalamic tissue, heavily infiltrated by leucocytes, the majority of which were polynuclear. At the edge of the abscess and localised to its edge were many granule cells loaded with lipoid. At the periphery of the abscess the cells stained well; at its centre cell-staining was absent. A few masses of Gram-positive cocci were found in the film of the pus. No organism was found on culture. Tubercle bacilli were not found. A small cholesteatomatous mass was found lying on the postero-superior surface of the petrous temporal bone just internal to its junction with the squamous temporal. Both middle ears contained thin pus. No sign of temporo-sphenoidal meningitis or thrombophlebitis was found. The mastoid cells were normal. The immediate cause of death was acute hæmorrhagic cystitis and consecutive pyelo-nephritis.

CASE 2.—Male, aged 12, had pneumonia and an empyema at the age of 7, from which he apparently made a complete recovery. He was considered to be in normal health until two and a half weeks before his death. About this time he had headache and vomiting for four days, and wandered a little at night. He became drowsy and irritable. A week before his death he had four epileptiform convulsions during the course of 24 hours, and following this he developed ptosis of the right eye and very marked stiffness of the posterior cervical muscles. He gradually became semi-conscious and later comatose. He died after a series of convulsions. No sign of aural disease was found, but well-marked papillœdema was present in both eyes. Whilst in hospital his temperature varied between normal and 99° F.; the pulse between 56 to 88. No sign was found to localise his cerebral condition.

Cerebro-Spinal Fluid.—Eight days before his death, when the clinical diagnosis was in considerable doubt, lumbar puncture withdrew fluid under considerably increased pressure, having the following characters: Clear with strong illumination, and colourless against a white background; 12 cells per c.mm. Differential count: 75 per cent. polynuclear, 20 per cent. "gitterzellen," 5 per cent. small lymphocytes. Total protein, 0·045 per cent.; chloride and sugar contents within normal limits. A cerebral abscess was suggested as the cause of the symptoms, chiefly on the analogy with Case 1, and five days later another sample of fluid gave the following result: Colourless; a fine opalescence by strong indirect illumination; 48 cells per c.mm. Differential count: 40 per cent. polynuclear, 30 per cent. "gitterzellen," 30 per cent. lymphocytes. Total protein 0·06 per cent.; sugar and chloride within normal limits.

Post-Mortem Examination.—The right pleural sac was obliterated. The right lung showed collapse and fibrosis of long-standing. Leading into its lower part three dilated bronchial tubes were found, whose mucous membrane was thickened, reddened, and velvety. A large abscess was present in the right frontal lobe of the cerebrum, replacing most of the anterior and inferior parts of the lobe, and pushing back and compressing the head of the caudate nucleus. It had not ruptured, but there was a patch of localised meningitis at the frontal pole, and the ventricular wall was obviously softened and infiltrated anteriorly.

Remarks.

In both these cases a cerebral abscess was found post mortem which had not discharged its contents into the ventricular system or sub-arachnoid space. The cerebro-spinal fluid was first examined, in each case at a time when it was absolutely clear, and when the clinical diagnosis was doubtful. At this time, in each case, the cell count was found to be 12 per c.mm. Even when one bears in mind the constancy of the cell count in normal spinal fluid, and the accepted fact that any figure over 5 per c.mm. constitutes a pathological increase, it is difficult to persuade oneself, when searching for a diagnosis at the bedside, that an increase of 7 cells per c.mm. has any great weight. The cell count of these fluids was less striking, however, than the fact that the cells responsible for the increase were polymorphonuclear leucocytes and foreign to normal spinal fluid, whilst the steady increase in the numbers of these cells during the progress of each case justified the importance attached to their presence when their numbers were so few.

In both cases it happened that a diagnosis of cerebral abscess was suggested without any knowledge of the clinical facts of the cases, but no claim is made that the presence, in a non-meningitic and blood-free spinal fluid, of polynuclear leucocytes, is alone diagnostic of abscess. All experience is against basing a clinical diagnosis on the result of an examination of this fluid alone, but it seems probable that, if a careful differential count of the cells shows the presence of polynuclear leucocytes even in small numbers, we have evidence of considerable positive value. It is generally taught that if, in a case with symptoms of acute cerebral irritation and pressure, a moderate degree of pyrexia, and a leucocytosis in the blood there are no changes in the spinal fluid, the strong presumption is that the condition is one of intracranial abscess.

It is likely that a careful differential count of the cells of the spinal fluid in many such cases would show a slight polynuclear pleocytosis and afford evidence of a positive nature which must always be of greater value than the negative characters of the fluid on which it is usual to base the diagnosis of abscess in its early stages.

A cerebral tumour, producing a vascular reaction in the meninges of the surface of the brain, may give rise to slight pleocytosis in a blood-free, non-meningitic fluid, and the cell increase may be due to a predominance of polynuclear leucocytes. In some cases the combined clinical and pathological evidence will not be sufficiently strong to differentiate abscess from tumour. In two cases of frontal tumour, recently observed, in which a vascular reaction was present in the soft membranes overlying the tumour, slight pleocytosis was found in the fluid and a high percentage of polynuclear cells, but in each case the fluid, when viewed in a strong light against an opaque white background, was unmistakably tinged yellow.

A spinal fluid which is clear and contains glucose and chloride in normal amounts is usually accepted as being non-meningitic, and it seems likely that, in cases more favourable to surgical interference than those quoted, the discovery of even a slight polynuclear pleocytosis in a colourless, non-meningitic, and absolutely blood-free fluid, especially if confirmed by repeated examinations at short intervals, may be of considerable service in diagnosis and treatment.

I am indebted to Dr. J. Odery Symes and Dr. Newman Neild, physicians to the General Hospital, Bristol, for permission to use their clinical records of these cases.

Clinical and Laboratory Notes.

A CASE OF MINOR SURGERY OF THE HAND.

By J. W. Tomb, O.B.E., M.D., D.P.H, Dub.

With reference to the leading article on the Treatment of Infections of the Hands in The Lancet of August 18th, and to the observation at the discussion on the subject at the annual meeting of the British Medical Association at Portsmouth that in women, for æsthetic reasons, every effort should be made to avoid disfigurement, I desire to place on record a case of minor surgery of the hand which though traumatic and not infective in origin will, I hope, prove of interest in this connexion.

One evening while the writer, who at the time had just qualified, was on accident duty in hospital, a female child of about 5 years of age was brought by her mother into the out-patient department suffering from an injury to the right index finger. On examination it was found that the terminal phalanx had been completely severed through the joint with the exception of a narrow strand of skin and tissue on the inner side by which the phalanx was still hanging to the rest of the finger. To have snipped through the connecting skin and tissue with a pair of sterilised scissors would have been the work of an instant, all bleeding having ceased, but as it was the right hand which was involved and the child was a girl, it appeared to the writer that a desperate effort should be made to save the phalanx on the chance that though almost completely severed and at the time both cold and to all appearance dead it might be able to be kept alive artificially in warm saline solution until the blood-vessels in the connecting strand of tissue had had an opportunity to increase in size if possible sufficiently to provide for the permanent nourishment of the part.

The hanging phalanx was accordingly brought into line with the rest of the finger and retained roughly in position by three stitches one on each of the severed sides. The finger was then bandaged and the child's mother instructed that she must remain awake all night and while the child slept must keep the bandaged finger continuously immersed in a bowl of warm saline solution—to be made by adding a teaspoonful of salt to a pint of warm water. She was further instructed that she must on no account allow the temperature of the water to fall below blood heat, and that on her zeal depended whether or not the child's finger was to be saved She was also instructed to bring the child back to hospital f inspection the following morning so that the phalanx coul be removed if dead.

On the child being brought back next morning, though th part was still cold, blanched, and apparently lifeless, it wa not possible to state categorically that it was dead, and s after re-dressing the finger the mother was again instructe to carry on the same treatment continuously during th succeeding 24 hours and to bring the child back for r inspection the following day. On the child being brough for re-inspection it was at once evident by the change colour in the part that the circulation was succeeding i re-establishing itself, and that the blood-vessels in th original connecting strand of tissue were in all likelihoo going to prove sufficient for the future nourishment of th part. The finger was re-dressed and further anxiety regardin the immediate progress of the case laid aside.

The after-history was uneventful, the phalan "growing on" again without suppuration, leaving finger of normal appearance but with a stiff distal joint

A CASE OF
UNUSUAL HÆMORRHAGE FOLLOWING A RADICAL MASTOID OPERATION.

By H. Lawson Whale, M.D. Camb., F.R.C.S. Eng.

OTO-LARYNGOLOGIST, HAMPSTEAD GENERAL AND LONDON TEMPERANCE HOSPITALS.

The following case is recorded because dangerou bleeding after a radical mastoid operation must b happily rare in the experience of any aurist.

At the Hampstead General Hospital on July 5th, 1923, performed what appeared to be a very ordinary radica mastoid operation on a male aged 23. There was no histor of hæmophilia, and during the removal of the patient' appendix six months earlier there had been no notabl bleeding; moreover, his coagulation-time had then bee found normal. During the mastoid operation there was n excessive hæmorrhage. The most frequent site of activ bleeding is a point deep to the lowest part of the concha— the spurt coming from a large branch, or more rarely the mai trunk, of the posterior auricular artery—when the meata flap is cut. But in the present instance even this stage of th operation gave no trouble.

On the evening following operation, and again on July 6th 7th, 10th, and 11th, the cavity repeatedly filled with blood soaking the dressings. On the 6th the post-aural stitches were removed, and on this and each subsequent day when bleeding occurred the cavity was re-packed, this proceeding involving a considerable loss of blood. On July 7th, under a light general anæsthetic, deep under-running sutures were inserted at the lowest part of the wound, to control the bleeding area. Between the 5th and 11th injections of hæmoplastin, subcutaneous and rectal salines, and calcium lactate by mouth, were consistently given with no avail.

On July 12th, one week after the operation, his general condition was extremely grave. A general anæsthetic was given; on removal of the packing there was a free intractable ooze of blood. The edges of the wound by now resembled sodden blotting-paper, and obviously no ligatures nor under-running sutures would hold. I therefore tied the external carotid (which arose from a high bifurcation close to the parotid gland) through a clean incision.

The subsequent history was one of slow but uneventful recovery.

THE "ETERNAL (PLASTIC) TRIANGLE."

A SIMPLE CURE.

By H. D. Gillies, C.B.E., F.R.C.S. Eng.,

SENIOR SURG., QUEEN'S HOSPITAL FOR FACIAL INJURIES, SIDCUP.

The problem of suitably closing small triangular gaps, or of fitting triangular points of skin into V-shaped spaces, must be of very common occurrence to all surgeons engaged in plastic or reparative work. However carefully suturing by the ordinary methods is carried out, some small residual triangle usually results and the more numerous the sutures used in the attempt to obliterate this the more is trouble from local necrosis likely to ensue. Reference to the

THE "ETERNAL (PLASTIC) TRIANGLE."

FIG. 1.

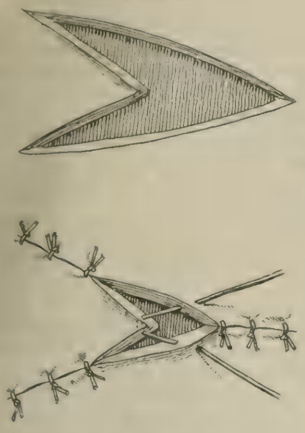

FIG. 2.

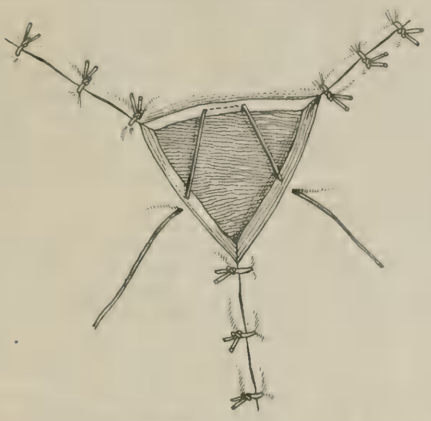

FIG. 3.

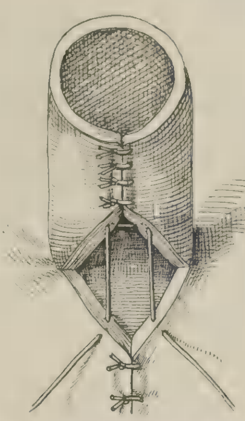

accompanying diagrams will make clear a method which has given absolute satisfaction in such cases.

Fig. 1 illustrates the way in which the point of a triangular flap is picked up subcutaneously by a skin suture passing between the other two sides, while Fig. 2 illustrates how one side of a triangle is similarly treated. Care must be taken to see that the points at which the needle penetrates the cut *edges* are all at the same depth from the skin surface. Fig. 3 illustrates the application of the same principle to the closure of the quadrilateral space at the extremity of a tube pedicle flap.

ROYAL SOCIETY OF MEDICINE.

SECTION OF PATHOLOGY.

A MEETING of this section was held on Oct. 16th, when Dr. JAMES YOUNG read a paper, illustrated by micro-photographs, on

Further Observations on the Ætiology of Malignant Disease and the Leukæmic Phenomena.

He stated that in cancerous tissue there were rounded or oval yeast-like bodies which could be seen to germinate when the tissue was incubated. Whilst adapted to the living tissue they were ill-adapted to the test-tube and became rapidly changed into elements suited to the new environment. In this way a cocco-bacillary flora was obtained which was easily stabilised on the laboratory medium. During its germination the yeast-like body became pale and in the "plasm" minute granules appeared which subsequently enlarged into the familiar flora. Thin threads and filaments frequently appeared as an intermediate phase. Dr. Young had long believed that the organism locked up in the cancerous tissue had the characters of a fungus. He described a fungus which he had obtained from seven cancerous tumours. This was stable on a dry medium, possessing branching hyphæ and conidia, but in a fluid medium was extremely unstable and rapidly broke down into cocco-bacillary elements. During the process yeast-ike, "plasm," and filamentous phases were common, and in every detail the morphological picture found n the incubating cancerous tissue was reproduced. njection of the bacillary phase of the organism obtained from mouse cancer produced in mice a diffuse and progressive neoplastic lesion (pseudo-eukæmia or lympho-sarcoma) in which the organism appeared not in the form of the bacilli injected but as yeast-like elements. By incubating the affected issues these rapidly became transformed into cocco-bacillary elements and the morphological process was again similar to that in incubating cancerous tissue. Dr. Young submitted that the investigations of Hort, Löhnis and Smith, Mellon, Almquist, Reid and Orr, de Negri, and others had proved beyond doubt the varying morphology possessed by familiar laboratory bacteria, which were to be looked upon as stabilised phases of organisms which in other conditions of growth possessed "plasm" and blastomycete characters. Dr. Young said that the organism used for his experimental injection was a lactose fermenter, belonging to the *Bacillus coli* group. From the chronic lympho-sarcomatous lesions, on the other hand, in the majority of cases a non-lactose fermenter belonging to the Salmonella group was obtained. The original organism produced a slowly progressive neoplastic lesion, the latter produced an acute, rapidly fatal lesion, although in its gross anatomy this might resemble the other. The sequence of the experiment implied clearly that the non-lactose fermenter was a secondary invader or that it was a mutant. If the latter were true it meant that cancer and the leukæmic phenomena were linked up with the typhoidal infections. In this connexion it was striking to note that the typhoidal lesion was essentially proliferative and might possess true malignant properties (Mallory) and that the possibility of the leukæmic phenomena being related to the typhoidal infections had already been mooted (Ewing). Dr. Young gave reasons for his belief that in the healthy animal the only cells that could after infection proliferate in a tumour-like fashion were the primitive cells. This finding had a striking analogy in the parasitic tumours of plants. It explained the leukæmic phenomena and at the same time the difficulty of producing cancer by artificial infection. It had long been recognised that a lengthy preparation of the mature cell was necessary for cancer to occur, and Dr. Young described experiments supporting his view that chronic irritation (tar, soot, heat, X rays, &c.) operated by throwing the mature cell back to the primitive state when alone infection would produce cancer. In each of four experiments comprising in all 152 mice, the animals were divided into two batches. One lot was vaccinated with the organism of the research, the other was kept as controls. All the animals were painted with tar twice weekly. The results were: After seven months in 76 controls there were 25 tumours, whereas in 76 vaccinated animals there were only five. These experiments supported the view that tar cancer was due to infection of damaged cells by an organism which was a common denizen of the laboratory cage.

Dr. E. H. KETTLE gave a communication on

Experiments with Defatted Tubercle Antigen.

He said that on analysing Prof. Dreyer's original paper it seemed that the claim that the new antigen was efficacious in the treatment of tuberculosis rested mainly upon the treatment of four guinea-pigs which had been infected with a strain of tubercle bacilli of low virulence. The evidence that the course of the disease was favourably influenced by the treatment was: (1) the increase in weight of the animals; (2) the diminution in size or disappearance of palpable lesions; and (3) the fibrosis and scarring of lesions in such animals as died. Dr. Kettle's experiments showed that these changes could occur naturally in guinea-pigs infected with tuberculosis without any treatment at all; further, that the most intense sclerosis and scarring of tuberculous lesions in one part of the body might be associated with the rapid progress of the disease elsewhere. Dr. Kettle's attempts at treatment of guinea-pigs had been carried out with an antigen (No. 58) given him in June by Captain S. R. Douglas, F.R.S., who had himself received it from Prof. Dreyer. Recently Captain Douglas had reached the conclusion that this particular batch of antigen was unsatisfactory, and that no great reliance could be placed on the results obtained therewith. Dr. Kettle said that the results of his own experiments were in any case ambiguous; some of the animals showed healing of lesions, but this was associated with active progress of the disease elsewhere. The general conclusions arrived at by him were that in view of the nature of the lesions to be seen in his control animals, which were demonstrated, the efficacy of the antigen in the treatment of tuberculosis in guinea-pigs had not been established; and that in view of the natural healing which tends to occur in these animals, comparable to the changes familiar in human pathology, much sharper reactions must be obtained before the value of any antigen could be considered as demonstrated experimentally.

Dr. J. **FREEMAN** made a communication on

Pollen Antigen Prepared by Dreyer's Method.

He said that it seemed interesting to try whether Dreyer's technique for the defatting of bacterial vaccines preparatory to constructing an antigen from them would prove a useful method for the defatting of grass pollen before extracting an antigen from it. The interest lay in the fact that the strength of the grass pollen antigen could be very accurately determined by suitable experiments on the skin of sensitive—i.e., hay-fever—subjects. For years the process of defatting the pollen before extraction had been carried out regularly, and it had only essentially differed from the full Dreyer technique in that there had been no initial fixing with formalin. This was, of course, the one point in which Dreyer's technique had differed from the previous work of Captain Stewart Douglas. Five grammes of pollen were extracted by Dreyer's method, and two other specimens of 5 g. were extracted as controls, one of them in exactly the same way as the Dreyer method minus the formalin, the other in the more usual manner of the laboratory. The preparations were tested on a number of patients and on a number of different occasions. The extract made according to Dreyer proved itself to be from 200 to 1000 times weaker than the other extracts. This would suggest that either the antigen was extracted in the formalin, or else that the formalin combined with and spoilt the antigen. If anything comparable happens in connexion with the tubercle bacilli it showed that the Dreyer defatted vaccine was very much weaker than the bacillary emulsion, which to Dr. Freeman's way of thinking might very well be consistent with its being more effective.

SECTION OF DERMATOLOGY.

A SPECIAL meeting of this section, to which members of the Neurological Section were invited, was held on Oct. 18th, Dr. E. G. **GRAHAM LITTLE**, the President, being in the chair, to hear an address by Prof. J. A. **FORDYCE**, Columbia University, New York, on

Results of Treatment of Syphilis of the Nervous System.

Prof. Fordyce said that observations as to the final results of incompletely cured cases of early neur syphilis had led his colleagues and himself to car out a rather extensive and prolonged study as to t probable relationship of the early types to the la degenerations. As a result, they were led to belie that the incidence of incurable types might be reduc to a minimum by proper diagnosis, treatment, an control of early cases. Only within the last te years had it been shown how frequently the spir chætes enter the nervous system during the peric of their dissemination by blood and lymph; it wa found that fully 25 per cent. of all syphilitics pr sented clinical or laboratory evidence of involvemen of the nervous system in the first year of infectio Many clinical observations were on record in whic patients with late syphilis of the nervous syste reported the occurrence of ocular palsies, bladd and rectal disturbances, paræsthesias, changes i the deep reflexes, and other signs of early implic tion. These symptoms regressed under treatmen but usually recurred in a more pronounced mann until a well-defined type was established. He ha been able to follow the life-history of several patient from the early months of their infection with positi evidence of cord and brain syphilis, until the develo ment, some 20 years later, of typical tabes an paresis. In cases in which modern therapeut methods had been employed and controlled by spin fluid examinations, cures without relapses had bee achieved. His colleagues and himself had been abl in their private and public work, to control, b clinical observation and laboratory tests, so-calle cures in many patients treated in a routine mann during the early infection, and he was convinced tha the large majority whose nervous systems wer implicated at that time, retained the infection though symptoms might temporarily disappear an the blood Wassermann become negative. Failure t control the infection in the central nervous system by systematic spinal fluid tests, led to the persistenc there of residuals which later became activated Longer use of the arsphenamine preparations intra venously, if their effects were controlled by flui examinations from time to time, cured certain type of early and late neuro-syphilis. On the other hand they had had cases in all stages of the infectio which failed to respond to drugs by the ordinar channels, but rapidly yielded to combined intra venous and intraspinal injections or to intraspina treatment alone.

Obviously, any prophylactic measure which migh prevent or lessen the incidence of neuro-syphilis should receive serious consideration; if lumba puncture were limited to cases with obtrusive signs irreparable damage might result. In over 1000 case of syphilis in which lumbar punctures were made i his clinic, 38 per cent. showed positive findings i the first two years. In one group there was a relatively low cell count, a slight excess of globulin a positive Wassermann reaction in the low dilutions and a luetic gold sol. curve. The minor cases wer amenable to routine treatment; they did not progress, and there were only slight nerve signs. In other groups of cases the most frequent symptoms were headache, vertigo, insomnia, nervousness, pains in the extremities, phobias, and inability to concentrate. Optic and auditory nerves were occasionally found to be involved, also pupillary irregularities, and deep reflex alterations. Several malignant cases were encountered, giving the picture of an acute meningitis, and some of these ended fatally. Experience had shown that in these malignant cases it was best to begin treatment with small doses, and relieve the pressure by spinal drainage, before proceeding to energetic measures. He and his colleagues believed that the nervous system might continue to harbour spirochætes, and yet all tests might be returned as negative. Still, these exceptional cases did not alter the general rule that the spinal fluid reflects the pathological processes in the brain and cord, and enables a differentiation to be made from non-syphilitic affections giving a similar clinical picture.

The nervous system might for years be the habitat of the spirochætes, and show little or no tissue reaction until a traumatism or other excitant stimulated their activity. A slight character defect, loss of ambition, forgetfulness, irascibility, mental depression, neurasthenia, often preceded for years the final stages of the paresis. The number of cases of syphilis of the nervous system was much greater than statistics revealed, as the figures were based on cases showing the classical syndrome.

A comprehensive re-study of the symptomatology in correlation with the findings in the laboratory they had found to be necessary before a rational prognosis could be made, and a logical treatment devised and carried out. The absence of the paretic gold sol. curve, in most of the cases, definitely excluded paresis. All who had wide experience in syphilis occasionally met with a patient presenting typical Argyll Robertson pupils, absent knee-jerks, with ninor sensory disturbance, and but little disturbance n gait, and in the cases of the kind examined the blood and all the findings in the spinal fluid were negative, and had remained so for several years. The possibility of the arrest of tabes by the ordinary outine treatment, or by the defensive forces of the body should encourage practitioners in their therapeutic efforts. In a clinical and serological analysis of 442 cases of neuro-syphilis in his private work during the past ten years, 156 patients with tabes were investigated, 50 of them in an early stage, with ncomplete findings of posterior column involvement, while 106 were sufficiently advanced to give the classical symptoms. In 70 per cent. the Wassermann eaction was positive in the blood, and—with one xception—positive in the fluid when larger quantities were used in the test. Twenty-five per cent. had a aretic gold sol. curve, and 75 per cent. a luetic one. The cell count varied from normal to 350. Of these ases, 30 had been re-examined, and had remained ee of symptoms on serological examination for om one year to nine years. Thirty-seven cases were not re-examined; in addition, 68 cases showed arked clinical improvement. The larger number f cases of neuro-syphilis were referred to Prof. ordyce by physicians who had treated them more r less intensively in a routine manner with salvarsan nd mercury, without antecedent fluid examination, it was not always possible to know the extent to hich the fluid findings were influenced by intraenous treatment alone. In the case of patients who ad become intolerant to salvarsan intravenously, ey had been obliged to employ intraspinal treatent with serum obtained from another treated tient. In this way proof of its spirochæticidal tion was obtained, uncomplicated with other ctors. Dr. Swift had given him the history of a pical case of tabes treated by Dr. Ellis and Dr. wift in 1913, by serum intraspinally, without intraenous injections. He was examined ten years after s last treatment, and his fluid findings were both egative, and his tabes had not progressed. The efinite response of certain types of neuro-syphilis intraspinal treatment after failure of the prolonged se of the intravenous route was confirmed by long inical experience and by careful laboratory control. ersistent intraspinal treatment when indicated by the uid findings could often preserve useful vision in optic rophy resulting from basilar meningitis. He gave tailed statistics of the ocular cases which had come der his care.

For the purposes of comparative study, he and his lleagues had grouped their 442 cases under the lowing tentative diagnoses, based on the clinical d the laboratory findings: (1) Secondary neurophilis; (2) vascular and meningo-vascular; (3) prebes or *tabes imperfecta*; (4) tabes well developed; optic atrophy and general paralysis. 365 of the 2 cases had been examined from one to ten years er treatment was discontinued. Nineteen cases secondary neuro-syphilis were treated intraspinally ause of the persistence of their symptoms and the t that there were fluid findings after from one to three courses of salvarsan given intravenously and mercury intramuscularly. Wassermann was positive in all cases, either in the blood or the fluid; in a large majority in both. The cell-count ranged from normal to 940. Five of the 19 cases received more than one course of combined intravenous and intraspinal treatment; eight had more than two courses; five had more than three courses. One patient, who was sensitised to salvarsan intravenously, was treated intraspinally only, and received 67 injections before securing a cure. In all the 19, the headache, insomnia, vertigo, aphasia, and facial palsy disappeared. Those which had marked tendon and pupillary changes had them still. In every case the reaction became negative in the blood, and in only two cases remained weakly positive in the fluid. The 17 patients who were serologically negative, had remained so for from 18 months to six years. Under vascular and neuro-vascular and neuro-syphilis he had included 139 cases which came under observation after two years from the primary infection, the signs being too indefinite to place them in the tabetic or paretic groups. In 25 the reaction was negative in the blood, and the diagnosis might have been missed if a complete examination had not been made. Sixteen had a negative reaction. Intraspinal treatment was used only when the fluid findings were positive. The speaker showed by a series of tables that the number of cases considered to be cured became progressively less with the age and the type of the infection. Of 116 cases of paresis treated intensively, 39 died, 30 had passed from observation, and 47 were known to be still living. He could not report any cures, though remissions were induced in 46 patients, the intervals lasting from a few months to several years.

Before he left New York treatment had been begun with the new arsenical preparation tryparsamid in a number of paretics; he could not yet pronounce as to its value. A preliminary drainage was not essential, and only the quantity of spinal fluid necessary for the tests had been removed in the cases under his care. Into the receptacle attached to the spinal puncture needle, 30 to 40 c.cm. of fluid was allowed to accumulate, and to this was added the inactivated serum. The mixture was then allowed slowly to re-enter the subarachnoid space by gravity. Thus, about one-third of the entire quantity of spinal fluid was mixed with salvarsanised serum before its reinjection. Half an hour after the preliminary intravenous injection was, they found, the best time for removing the blood. This was permitted to clot overnight in the ice-box; next morning it was centrifugalised and the serum pipetted into a sterile tube. This was repeated to remove all red cells, and the clear serum pipetted into another tube and heated for 30 minutes at 56° C. The intervals were never less than two weeks, and were gradually lengthened until six or eight injections had been given. Six weeks to two months were allowed before a second series was commenced. Numbness in buttocks and genital organs, with difficulty in urinating, must be taken as indications to discontinue the treatment, or at least observe longer intervals between injections.

Conclusion.

Prof. Fordyce summarised his conclusion as follows: Mostly, the central nervous system is invaded during the general dissemination of the virus. Often it was checked, seldom cured, by the usual therapeutic methods. Late neuro-syphilis is not due to reinfection from foci outside the nervous system, but to long persistence *in loco* of the infecting organism. If the nervous system was not involved early in the infection, probably it would not be involved later; this with the exception of vascular lesions and gummata. In the presence of a persistent Wassermann, the possibility of a nervous system lesion should be remembered. Treatment should not be stopped without information from lumbar puncture. Certain types of nerve syphilis were more rapidly controlled by combined intravenous and intraspinal treatment, and sometimes only by this method. In general paralysis remissions of long duration were achieved which were more striking in patients with a pronounced meningeal reaction. Cures could not be attained by any existing treatment.

Discussion.

The President expressed the warm thanks of the meeting to Prof. Fordyce for his valuable address.

Dr. James Collier said Prof. Fordyce saw cases at an earlier stage than seemed the general experience in this country, and the lecturer and his colleagues treated the cases from the moment they appeared, even before they showed neurological symptoms. He heartily agreed with the view that invasion of the nervous system occurred in very early days. It was remarkable how long the virus might remain latent. One case he knew acquired the disease at 18 years, and his first neurological symptom supervened at the age of 61. He would like to know how soon after primary infection tabes might develop; he had known cases in which virulent and progressive degeneration of the nervous system occurred within a number of months after the primary infection. Prof. Fordyce seemed to have attained amazingly favourable results. Optic atrophy from gumma on one side was often arrested, but he had never known a slow diminution of vision from neuronic degeneration cured.

Prof. F. R. Fraser agreed that the results obtained by Prof. Fordyce in New York were largely due to the very thorough treatment he had carried out. Many workers maintained that the results of lumbar puncture combined with intravenous injections were good without the intraspinous use of salvarsanised serum as well. Two series treated by the two methods would form an interesting comparison. The lesson of the address was a definitely valuable one, as he felt sure the general profession did not sufficiently appreciate the early involvement of the nervous system by syphilis.

Dr. Ellis considered the work detailed by Prof. Fordyce to be one of the biggest presentations on the subject he had ever heard. When a man said intravenous treatment did not benefit neuro-syphilis, it could generally be safely assumed that he had been giving an inadequate amount, and so with other treatments. And here the thorough treatment of these cases was a question of man-power; the amount of work for each man to look after in our hospitals was much greater than in New York. There was very strong probability that dissemination of the virus to the nerve and other structures took place during the period of septicæmia. In his own original series all the cases which resisted treatment and in whom the signs of infection persisted had since died.

Dr. G. Riddoch referred to rare cases in which, though the clinical and serological tests became negative, the patient continued to go downhill; these required serious investigation. He had great praise for Prof. Fordyce's work and the extraordinarily good results he had achieved.

Dr. J. H. Sequeira said the work done long ago by Head, Fearnsides, and others, showed that the spinal cord and brain were affected in very early stages of syphilis; and all the available knowledge showed how important it was to commence treatment for syphilis at the earliest possible moment. It devolved on all in charge of syphilis clinics especially to take the lesson to heart. By attention to the points insisted on by Prof. Fordyce, there was hope that the greater part of neuro-syphilis might be stamped out.

Dr. H. MacCormac remarked that it might be said the neurologist saw the failures of the dermatologist in this disease. In his own clinic all the cases of early syphilis were examined in regard to the cerebro-spinal fluid, and in most cases this fluid showed no evidence of the disease after a complete course of treatment; yet it did not follow that at a later period they would not show some of the remote sequelæ. This contribution should encourage dermatologists to persist in the treatment longer than they did at present.

Dr. Wilfred Fox combated the statement sometimes heard that neuro-syphilis was produced by instituting more active treatment.

Dr. A. M. H. Gray also thanked Prof. Fordyce for his contribution, and dealt with the proportion he gave of secondary cases in which there was evidence of neuro-syphilis, comparing that with the figure obtained in pre-salvarsan days.

Prof. Fordyce briefly replied.

MEDICAL SOCIETY OF LONDON.

Exhibition of Cases and Specimens.

A clinical evening of this Society was held at 11, Chandos-street on Oct. 22nd, with Dr. Herbert Spencer, the President, in the chair.

Pituitrin in Diabetes Insipidus.

Dr. Batty Shaw showed two cases of diabetes insipidus, illustrating the value of treatment by hypodermic injections of pituitrin. The first, a man, had been passing as much as 18 pints of urine a day for a considerable period before he sought advice. There were no signs of nervous lesion, an X ray of the skull showed no change in the pituitary fossa, and the metabolism was normal; 2 c.cm. of pituitrin a day administered hypodermically had reduced the urine output to almost normal dimensions, but its use had been followed by multiple subcutaneous abscesses, thrombosis, and infarction of the lung from which the patient was now happily recovering. The second case, a female, was interesting, as in this case the polyuria had followed a definite glycosuria which had now disappeared; 1 c.cm. of pituitrin daily was sufficient to control the symptoms in this case.

Dr. K. S. Hetzel, who continued the description of the cases, said that in both cases the blood-sugar was raised, but there was no glycosuria. The basal metabolism in the first case was lowered as was the rule when the disease was well established, and in the second case, which was of recent origin, was raised 18 per cent. The action of the pituitrin was apparently on the kidney.

Dr. F. J. Poynton had treated a child, aged 11, who was passing 280 oz. of urine a day and was really very ill, with pituitary extract with great benefit. Pituitary extract was useless unless given hypodermically.

A Case of Cerebral Tumour.

Dr. G. Riddoch showed a woman, aged 32, who had exhibited a left hemiparesis and hemianæsthesia, with headache and vomiting during each of her five pregnancies in the last eight years. In August this year, when she was admitted to the gynæcological wards of the London Hospital for the sequelæ of a miscarriage, these symptoms were again present. Examination revealed papillœdema and constriction of the visual field on both the nasal and temporal sides, especially marked on the latter. The urine was normal. An X ray examination showed a normal sella turcica, but there was a change in density of the picture in the region of the anterior clinoid process. Since then the hemiparesis and anæsthesia had disappeared almost totally, but the visual defect and headache remained and the patient was becoming obese, having put on a stone in weight since being discharged from hospital. He thought there could be little doubt that there was a cerebral tumour; the case exhibited well the exacerbations and remissions which might occur in the progress of this disease.

Carcinoma of the Pharynx.

Mr. E. D. D. Davis showed drawings of five cases of carcinoma of the pharynx: (1) an early epithelioma of the base of the tongue; (2) an advanced excavating ulcer of the base of the tongue; (3) an early pyriform sinus epithelioma; (4) an early post-cricoid carcinoma, the larynx in this case had been excised by Mr. E. B. Waggett; and (5) an advanced post-cricoid epithelioma from a woman aged 38. It was curious that the pyriform sinus epithelioma was almost confined to the male sex, while the post-cricoid epithelioma was seldom seen except in comparatively young women whose symptoms were too often attributed to hysteria before the secondary glandular enlargement in the neck revealed the true nature of the case. Laryngoscopic examination was often very difficult, but these growths could easily be reached and felt by the finger. Mr. Davis also showed a radiogram of a pharyngeal pouch filled with a bismuth mixture, and gave an account of the case and the operative treatment employed.

Mr. **ARTHUR EDMUNDS** had also found the finger the most reliable guide to the diagnosis of pharyngeal growths; this examination was best made under general anæsthesia.

In answer to a question by the **PRESIDENT**, Mr. **DAVIS** said that radium, while cleaning up malignant ulcers of the pharynx and rendering life more comfortable for a time, had no curative effect. At least 200 milligrams should be employed for this purpose.

Acholuric Jaundice.

Dr. **POYNTON** showed a young woman, a case of this congenital disease, who had been under observation for 20 years. In the case shown fragility of the red blood corpuscles had never been demonstrable, although it was well marked in two other members of the same family who suffered from the same disease. The spleen was much enlarged. He showed her with a view to obtaining opinions as to the advisability of splenectomy.

Dr. **HERBERT FRENCH** thought the spleen should have been removed ten years ago, before the patient had come to her present low condition and the spleen to its very large size which rendered operation very risky. He had had a case of the same kind in a boy who, before splenectomy, was too ill even to attend school. After the spleen had been removed he recovered so well as to be able to serve abroad throughout the war; he was now married and had two children.

Dr. **PARKES WEBER** knew of a family similarly afflicted. One of the male members served abroad for some time, but had a relapse. Splenectomy was eventually performed and he recovered. On the other hand, the grandfather, who suffered similarly, lived to 74 without any operation. As the result of his observations in South Germany, where Perthe had obtained admirable results from splenectomy, he would now feel inclined to advise operation in selected cases when the services of a surgeon experienced in this operation were available.

Dr. **POYNTON**, in reply, said that ten years ago the patient was not under treatment—in fact, she had only presented herself on four occasions during 20 years for relapses, apart from which the patient was able to carry on her work. An elder brother had been able to work with a red blood count of only 1,700,000, and a sister of 30, who also suffered even more severely, had improved after marriage and had a healthy child. Under these circumstances he was averse to advising operation merely on account of the pain due to the spleen.

Congenital Heart Disease.

Dr. **T. JENNER HOSKIN** showed a girl, aged 8, who suffered from breathlessness on slight exertion. Examination of the heart showed the apex beat in the fourth intercostal space just external to the nipple, with a thrill and humming-top murmur systolic and partly diastolic in time over the aortic area. X rays showed slight enlargement of the heart to the left, while the electrocardiogram suggested a right ventricular preponderance. The sounds resembled those of a patent ductus arteriosus, but were heard on the wrong side of the chest; this he thought might be due to transposition of the great vessels without transposition of the heart. Two other members of the family, the father and a paternal uncle, were said to have suffered from congenital heart disease.

Melanotic Sarcoma.

Mr. **SAMPSON HANDLEY** showed a case of melanotic sarcoma. The primary tumour on the cheek had been excised locally, and glandular deposits were treated medically for some time before the case came under his care. The case now exhibited a number of metastases spread around the site of the primary tumour, the distribution of which suggested that dissemination occurred through the lymphatics, as in cancer of the breast. In further proof of the lymphatic spread of melanotic sarcoma he hoped to show on a future occasion a case of recurrent melanotic sarcoma still living on which he had operated 15 years ago.

Diverticulum of the Bladder.

Mr. **CLIFFORD MORSON** showed X ray photographs and the stones removed by operation from two cases of diverticulum of the bladder containing stones. The first case was cystoscoped for pyuria, and the diverticulum containing stones was observed. Subsequent operation, however, revealed an inoperable carcinoma of the pouch. The second case, a man aged 75 years, had had a prostatectomy performed by Sir Peter Freyer 18 years ago. Five years later a stone was removed by litholapaxy. The skiagram on this occasion showed 15 stones which were removed by suprapubic cystotomy. The pouch in which the stones lay was very large and adherent to the colon, so that its removal was not deemed feasible. In answer to questions, Mr. Morson said that carcinoma in a diverticulum containing stones was, contrary to what might be expected, very rare. At a recent meeting of urological surgeons only two cases of the kind could be recorded.

A Case of Myotonia Atrophica.

Dr. **JAMES PURDON MARTIN** showed a woman, aged 35 years, who suffered from this form of muscular dystrophy. She exhibited the characteristic wasting in the facial muscles, the sternomastoids, the muscles of the forearms and of the right thenar eminence, the extensors of the thighs, and the right calf muscles. Myotonia was shown in the hand grasp and in the reaction of the muscles of the thenar eminence to percussion. Absence of all the tendon jerks with preservation of the normal superficial reflexes was also demonstrated. There was an interesting association of this disease with cataract, which usually appeared in two or more preceding generations, and in this particular patient was exhibited by the grandfather and father. These patients also exhibited a change in temperament becoming "negativistic." The children of the myotonic generation appeared to be normal. The explanation of the tonicity combined with wasting in the muscles was difficult, but the electrical reactions showed that the muscles and not their innervation were to blame.

Plastic Surgery.

Mr. **ARTHUR EDMUNDS** showed three cases illustrating the results of plastic surgery. The first showed the closure of a gap in the cheek by sliding flaps of mucosa on the buccal aspect; such flaps, if properly fashioned, would heal almost as readily as similar flaps on a normal skin surface. In the second case, a pedicled skin flap from the abdominal wall had been employed successfully to make good the loss of skin resulting from a severe crush of the hand. A case of hypospadias successfully treated by fashioning a new urethra by stages from the prepuce was also shown. The method employed was described and illustrated in THE LANCET (1913, i., 447).

UNIVERSITY OF MANCHESTER.—Amongst those persons selected by the Earl of Crawford and Balcarres to receive honorary degrees on the occasion of his installation as Chancellor of the Victoria University of Manchester are Prof. J. G. Adami, F.R.S., and Sir Arthur Keith, F.R.S. Prof. F. E. Weiss, D.Sc., F.R.S., has been reappointed Pro-Vice-Chancellor for a period of two years.

Reviews and Notices of Books.

THE HEART IN MODERN PRACTICE.

Diagnosis and Treatment. By **WILLIAM DUNCAN REID**, A.B., M.D., Chief of Heart Clinic at the Boston Dispensary; Junior Assistant Visiting Physician and Member of the Heart Service at the Boston City Hospital. London and Philadelphia: J. B. Lippincott Company. 1923. Pp. 352. 25*s*.

THE central motif of Dr. Reid's admirable little book is summed up by these words in the preface: "The day of the consideration of heart affections from the viewpoint of the structural change or anatomical lesion has passed; of greater importance is that of the functional condition and perhaps even more essential, to an intelligent conception, is the recognition of the ætiological type." In pursuance of this policy the author has divided the main part of his book into three sections. These deal respectively with the types of heart disease from an ætiological standpoint, functional conditions, and, lastly, structural lesions. In the present state of our knowledge a complete and perfect ætiological classification of disease is, of course, impossible. But even a provisional classification on these lines is infinitely preferable to the older system, which was not merely unsatisfactory, but tended to raise up an artificial boundary between structure and function.

During recent years so many new facts have been added to the physiological aspect of cardiology that a comprehensive text-book which attempts to give a complete account of the subject must attain considerable dimensions. Dr. Reid has not attempted to do this; and in cutting down the subject to suit the average student he has used the pruning-knife very freely. He has, however, succeeded in maintaining throughout a very good sense of proportion, and has given a thoroughly up to date, if brief, account of a difficult subject. The method of delegating the illustrative cases to an appendix makes the text the more readable, and both Dr. Reid and his publishers are to be congratulated on having produced such an attractive and useful book.

A DICTIONARY OF TREATMENT.
